| 1899  | 9,765,616           | 72,825   | 14,891         | 756     | 9,780,497 | 73,581   | 1,739,036 | 13,836   | 759,691   | 14,342   | 6,484          | 462    |
| 1900  | 8,449,252           | 57,842   | 19,167         | 1,019   | 8,468,419 | 58,861   | 1,703,256 | 11,832   | 796,534   | 14,913   | 6,365          | 435    |
| 1901  | 8,546,691           | 83,196   | 16,738         | 918     | 8,563,429 | 84,114   | 1,466,431 | 12,510   | 1,106,553 | 18,294   | 12,861         | 1,004  |

(a) Includes 241,452 lb. entered as crude and 1,416,587 lb. as powdered. (b) In 1897 includes 14,471 lb. ground in oil and 1,433,418 lb. dry, crude or powdered; in 1898, 4,608 lb. (\$323) ground in oil and 1,118,471 lb. (\$8,726) crude, powdered, washed or pulverized; in 1899, 4,849 lb. (\$300) ground in oil and 1,734,187 lb. (\$13,066) dry, crude, powdered, washed or pulverized; in 1900, 11,653 lb. (\$728) ground in oil, and 1,691,608 lb. (\$11,189) dry, crude, powdered, washed or pulverized; in 1901, 3,184 lb. (\$173) ground in oil and 1,502,246 lb. (\$12,387) dry, crude, powdered, washed or pulverized.

Iron oxides and Venetian red are produced from natural and artificial sources, principally the latter in connection with the manufacture of copperas, which is made as a by-product from the spent vitriol used in cleaning wire and wire rods. The bottom crystallization of copperas is too impure to be disposed of in a commercial way and, as its use is limited, the greater part of it is converted by different processes into iron oxides.

The principal method of manufacture is called the "dry process," in which the copperas is roasted in a furnace with an admixture of lime or similar material to neutralize the acid in the sulphate, until the required strength and color are obtained. This method is considered the cheapest and quickest for the production of low grades of oxides. Copperas alone is roasted a sufficient length

of time until only the pure oxide remains, which is then reduced with the aid of a filler, as whiting, to form the different grades of Venetian red. Samples of this product sometimes have as little as 10% of iron oxide or coloring power. The dry process varies in details of furnace arrangement, crucibles, application of heat, etc.

There is also in use a "wet process," which is more economical, although the product is not as uniform as that produced by the dry process. By the wet process, the waste pickling liquor is treated direct for its iron content. Several patents have been applied for on the principle of passing steam direct to the waste acid solution for the purpose of oxidation, while in others, milk of lime, sodium carbonate, or other precipitant, is added to the waste liquor to precipitate the iron as a hydrate or carbonate, which is collected at the bottom of the tank and subsequently separated by passing the liquor and precipitate through filter presses, where all moisture is removed. The press cakes are roasted in furnaces, cooled and packed for the market without grinding. The product is of medium strength, not uniform, and can only be used for limited purposes. Apart from the above-mentioned methods, different colors and strength of oxides are produced by the addition of natural ores and others. Furthermore, iron ores in different parts of the country are also ground and sold direct as Venetian reds. The strength, color and fineness of natural reds, however, are inferior to the manufactured article and do not command as high a price. Considerable improvement has been made in the domestic product during recent years, and importations are decreasing. It is probable that nearly the entire domestic demand for high and low-grade iron oxides will be filled in the United States in the near future.

The principal manufacturers of iron oxides and Venetian red are: the American Steel & Wire Co., at Worcester, Mass., and Waukegan, Ill.; C. K. Williams & Co., Easton, Pa.; S. P. Wetherill & Co., Philadelphia, Pa.; Henry Erwin, Bethlehem, Pa.; Mephram & Klein, St. Louis, Mo.; and Hanna & Andrus Co., Chicago, Ill. There are also smaller producers in the country who devote their attention to the mined and natural reds only.

*Market.*—Prices in New York during 1901 averaged about \$13 per ton in barrels for the mined reds, some of those mined in Maryland and the South being offered at \$10. For the manufactured or copperas reds, prices averaged about \$22 per ton, while for the iron oxide red considerably higher prices were obtained, depending entirely upon the strength of iron and color. None of the domestic producers report having operated its works to its full capacity for any length of time on account of the production being in excess of the demand. It is also claimed that this business could not be operated profitably alone, but must be run in connection with another industry or as a means of disposing of waste material. There is but little opportunity for the development of export business as foreign mills manufacture iron oxides as a by-product besides producing natural reds and others.

Venetian reds and iron oxides are used principally where a low priced paint of durability is required, as for railroad, bridge and car work, roof and building paints, or as a preservative of iron. These paints are also used considerably in paper mills for sheathing-in color paper and in the manufacture of leather board.

## PETROLEUM.

By F. H. OLIPHANT.

A CONSPICUOUS feature in the world's production of petroleum for 1901 was the remarkable increase in the supply of the lower grades, and the gradual decline of the higher grades of mineral oil in the fields of the United States. The discovery of new sources of petroleum supply in the Southwest has greatly extended the area of our fuel oil territory, while the fields from which is obtained the more valuable illuminating and paraffine products, are slowly but surely becoming exhausted, and new territory is absolutely necessary in order to sustain the present annual output. The consumption of petroleum for fuel purposes is assuming very large proportions, and both Russia and the United States have greatly increased their output of this quality of petroleum. The lighter products are likewise finding more extensive use as illuminants and for motor purposes. A large demand has also been created for them as a gas oil. Several large refineries are now in course of construction near Philadelphia, which will manufacture an oil exclusively for gas purposes, from the inferior crude product of the Gulf petroleum fields—the residuum finding a market as a high test fuel oil.

### PRODUCTION OF CRUDE PETROLEUM IN THE UNITED STATES. (BARRELS OF 42 GAL.)

(a) Includes New York, Pennsylvania, West Virginia, and part of Ohio. The statistics of production in this field and the Lima field in Ohio as given in previous volumes of THE MINERAL INDUSTRY were based on the pipeline receipts reported by the *Oil City Derrick*. They have been changed in the present volume so as to represent the actual production. (b) Statistics of California State Mining Bureau. (c) Statistics of State Geological Survey. (d) Estimated. (e) The statistics for 1899 and 1900 were furnished by Mr. C. F. Z. Casaristi.

Natural gas has become an indispensable agent in the economical operation of oil wells in the older portions of the producing region. The application of the gas engine to pumping oil wells has greatly cheapened the cost of production, and made it possible to operate the smallest wells at a profit. A failure of the natural gas supply in the oil country would result in the immediate abandonment of thousands of oil wells with a great decrease in the production and an increase in the cost of bringing the crude petroleum to the surface.

The following table gives a careful estimate of the quantity of petroleum produced in the world in 1900 and 1901 by countries. There are a number of countries that produce petroleum to a small extent, from which it has so far been impossible to secure any reports, because the business is carried on in the most primitive manner.

PRODUCTION OF CRUDE PETROLEUM IN THE COUNTRIES OF THE WORLD. (a) (IN METRIC TONS.)

| Year.     | Austria. | Hungary. | Canada. | Germany. | India.  | Italy. | Japan.     | Russia.    | United States. |
|-----------|----------|----------|---------|----------|---------|--------|------------|------------|----------------|
| 1896..... | 262,356  | 2,164    | 101,682 | 20,395   | 60,228  | 2,584  | (b)81,314  | 7,105,768  | 8,502,187      |
| 1897..... | 275,204  | 2,299    | 99,310  | 22,303   | 75,834  | 1,962  | 42,184     | 7,691,254  | 8,513,149      |
| 1898..... | 323,142  | 2,471    | 98,044  | 25,789   | 71,627  | 2,015  | (c)59,980  | 7,641,671  | 7,764,718      |

| 1900..... | 347,218  | 2,199    | 91,189  | 50,464   | 140,064 | 1,668  | 64,508     | 10,534,919 | 8,928,408      |

(a) From the official reports of the respective countries. This table is only partially complete since it does not include the production of Roumania, Sumatra, Borneo, Java, South Africa, Peru, and some other countries.  
(b) Estimated from hectoliters. (c) Crude oil.

Petroleum is known to be produced and used to some extent in China, Persia, Turkey, and several of the South American countries besides Peru.

A general idea of the stocks on hand at the end of the year in the different districts may be gained from the following table in which the amounts are expressed in barrels of 42 gal. :—

| Appalachian. |            |            |           | Lima.      |            |            |            |

| 1900..... | 188,161          | 7,941   | 18,570    | 1,651   | 739,136       | 54,598   | 71,211                     | 9,983   | 19,750    | 845   | 986,855   | 74,498   |
| 1901..... | 127,008          | 6,089   | 21,638    | 1,743   | 827,222       | 53,491   | 75,291                     | 10,360  | 27,596    | 1,255 | 1,078,902 | 72,766   |

(a) In addition to the above, the following quantities of paraffine and paraffine wax were exported: 1897 135,069 lb. (\$5,284); 1898, 166,317 lb. (\$6,363); 1899, 181,861 lb. (\$7,650); 1900, 157,108 lb. (\$8,186); 1901, 151,695 lb. (\$7,930).

The average price of refined petroleum at New York in 1901 was 6·2c. per gal., as compared with 2·04c. per gal. at Batum and Novorissisk, on the Black Sea, which is a very wide difference in value between the two articles. Were it not for the superior quality of the United States product, as well as the superior methods of delivering the manufactured products, it would be impossible to market the quantity that is now disposed of. It must be remembered that a large percentage of the Russian refined petroleum is a by-product. Owing to the great demand for fuel petroleum, and as the crude cannot be marketed as such until the more volatile products are removed and the fire test is sufficiently raised to conform to the Government standard, it is necessary to pass it through the process of distillation, by which the smallest possible quantity is converted into naphtha and illuminating product. The much larger proportion is marketed for fuel under the name of "residuum" or "astatki."

The quantities of naphtha, illuminating, lubricating and paraffine oils exported from the United States and Russia in 1901, in gallons, were as follows:—

| Country.           | Naphtha.          | Illuminating.        | Lubricating and Paraffine. | Total.               |
|--------------------|-------------------|----------------------|----------------------------|----------------------|
| United States..... | 21,685,000        | 827,222,000          | 75,291,000                 | 984,198,000          |
| Russia.....        |                   | 828,732,480          | 38,450,820                 | 867,192,280          |
| <b>Totals.....</b> | <b>21,685,000</b> | <b>1,156,954,480</b> | <b>113,750,820</b>         | <b>1,301,390,280</b> |

The quantity of crude, residuum and distillate is omitted from both countries. Of the products named in the above table the United States exported 71% and Russia 29%.

The chief markets of the manufactured products exported from the United States, Russia and other countries are the United Kingdom and Germany.

The following is an official statement of the importation of petroleum and its products—illuminating and lubricating oils—into Great Britain for 1899, 1900 and 1901, in Imperial gallons, which are one-sixth greater than the United States gallon:—

IMPORTS OF PETROLEUM INTO GREAT BRITAIN. (IN ENGLISH GALLONS.)

| Countries.               | 1899.              | 1900.              | 1901.              |
|--------------------------|--------------------|--------------------|--------------------|
| United States.....       | 166,192,455        | 153,776,766        | 162,791,209        |
| Russia.....              | 69,816,972         | 87,765,897         | 78,207,884         |
| All other countries..... | 4,137,940          | 13,435,980         | 13,517,065         |
| <b>Total.....</b>        | <b>240,147,367</b> | <b>254,978,643</b> | <b>254,516,098</b> |

The total exportation for the past two years has been nearly the same in quantity, although it will be seen that the amount imported from the United States has decreased from 69% of the total importations in 1899, to 60% in 1900, and increased to 64% in 1901, as compared with 29% imported from Russia in 1899, 34% in 1900, and 31% in 1901. A comparison of the two last years shows that the United States is increasing the sale of petroleum products at the rate of 6% yearly, while that of Russia is declining at the rate of 11%.

The average price for the United States refined petroleum at Liverpool during 1901 was 7d., or 14c. per Imperial gallon—which is one-sixth larger than the United States gallon—as compared with 6·25d., or 12·5c. per gal. for the Russian refined.

The increase in quantity has been sold at higher prices for the American products, in the face of the fact that there is a very large amount of English capital invested in the Russian petroleum fields at Baku, which would naturally be interested in the sale of the Russian product within its own limits as against the interest of the other countries. The increase in the sales of the United States product must therefore be due entirely to the superior quality of the article which is sold on its merits alone.

The exports to Germany for the years 1899, 1900, and 1901, have been made up from the countries exporting the manufactured petroleum, and embrace the naphtha, illuminating and lubricating products in gallons exported from the United States and Russia.

REFINED PETROLEUM EXPORTED TO GERMANY BY THE UNITED STATES AND RUSSIA.  
(UNITED STATES GALLONS.)

| Countries.         | 1899.       | 1900.       | 1901.       |
|--------------------|-------------|-------------|-------------|
| United States..... | 128,074,790 | 141,626,015 | 150,261,515 |
| Russia.....        | 26,310,340  | 29,994,478  | 31,914,340  |
| Total.....         | 154,385,126 | 171,620,493 | 172,175,755 |

These figures also indicate the increasing consumption of the United States product. Of the total of these two countries, the United States furnished 83% and Russia 17% in 1899, as compared with 83 and 17% in 1900, and 87 and 13% in 1901. The price per United States gallon at Bremen averaged close to 9·5c. per gal. in 1901 for United States illuminating petroleum, and about 8·75c. for the Russian product.

In 1901 the United Kingdom and Germany together consumed 34% of the total exportation of the United States, as compared with 37% of the total Russian exportation. The combined exportation of these countries amounted to 313,053,412 gal. from the United States, and 100,122,124 gal. from Russia, making a total of 413,175,536 gal., amounting to 32% of the total exportation from the United States and Russia. The remainder found a market in other parts of the world.

The increase in the total production of petroleum in the world during 1901 over that of 1900 was 7,541,335 bbl., or 12%. Russia produced 51·4% and the United States 41·9% of the total output, leaving but 6·7% to be produced by all other countries. While this proportion holds true so far as the gross produc-

tion is concerned, it is not, however, a true comparison when the quantity and quality of the higher grades of illuminating, lubricating, paraffine products and other derivatives are considered. The amount of naphtha, illuminating, lubricating and paraffine products secured from the production of 69,389,195 bbl. of crude oil in the United States is estimated to be not less than 47,560,195 bbl., amounting to 1,997,520,000 gal. Of this amount 911,120,944 gal. were exported after deducting 151,629,462 gal. of crude, also exported. This represents 55% consumed at home, and 45% exported, while the average yield of manufactured products upon all the petroleum produced in the United States is 68.5%.

From the Russian field there were exported to other countries during 1901, 428,657,210 gal.; of this amount 14,534,990 gal. were crude and residuum, leaving 414,122,990 gal. of illuminating, lubricating, distillate and solar petroleum, as compared with 911,120,944 gal. of manufactured products exported from the United States. Therefore, for every gallon exported by Russia, the United States exported 2.2 gal., or 69% of the total manufactured products from petroleum are shipped abroad from the United States, as compared with 31% from Russia. Of the 85,168,555 bbl. produced in Russia, only 11,805,551 bbl., or 495,833,154 gal., were converted into manufactured products. This amount represents but 13.8% of the total production of crude in Russia, as compared with 68.5% of manufactured products obtained from the crude produced in the United States. In Russia 86.2% is consumed as fuel, while only 31.5% of the total production is consumed in the crude state in the United States.

Of the total manufactured products amounting to 13.8% in Russia only 15% of this amount was consumed at home, leaving 85% to be exported abroad, as compared with 55% consumed at home in the United States and 45% exported.

Russia and the United States produced 93.3% of the known output of petroleum in the world during 1901. The indications are now that Texas will redeem in a few years the place at the head of the list once held by the United States as the country producing the largest quantity of crude petroleum in the world.

The average price of the crude petroleum produced in the United States during 1901 was 95.1c. per bbl., and the total valuation was \$66,417,335. The average price paid for the Russian crude petroleum during 1901 was 32.67c. per bbl., the total value being \$27,824,567, which is only about 40% of the amount received from the crude petroleum produced in the United States for the same time.

These amounts added together give \$94,241,902 as the price of 154,557,750 bbl. of crude petroleum produced by these countries, which is an average value of 61c. per bbl. In all the other countries producing petroleum, viz.: Canada, Peru, Galicia, Roumania, Sumatra, Java, Borneo, Japan, India, Germany and Italy, only 11,160,770 bbl. were produced, amounting, as before stated, to 7.6% of the entire known production of the world. The estimated value of this quantity of petroleum at 70c. per bbl. is \$7,812,539. If this is added to the value of that produced in the United States and Russia, the total amounts to \$102,054,441 for the known production of the world in 1901, and if this be

divided by 165,718,520, the total production, the average price per bbl. of the world's crude petroleum output is 61.5c.

*Present Condition and Future Possibilities.*—The wide range in the producing area of petroleum in the United States, and the different conditions under which it is stored, indicate an increased production in the future. Slowly but surely the conditions under which it is concentrated are being more carefully studied, and the mechanical appliances for drilling, pumping and transporting improved. In no other country has the transportation of both crude and refined petroleum in trunk lines reached the perfection that has been attained in the United States. Triple expansion pumping engines have enabled the pumps to work up to a pressure of from 600 to 1,000 lb. to the sq. in., at a minimum cost of fuel. These trunk lines and their feeders extend over hundreds of miles and connect distant fields with the refineries and the large markets of the seaboard and inland cities. The future will, without doubt, produce methods of deep and rapid drilling at moderate cost, which will reach the deeply buried petroleum producing strata when the upper strata has been exhausted. In portions of the Appalachian region it will require 6,000 ft. to reach the lowest stratum that elsewhere is known to contain petroleum. The important work of the chemist in separating noxious vapors and deleterious combinations from the lighter products of the lower grades of petroleum, producing from them superior lubricating oils, must also be a work for the future.

*Geology.*—The geological equivalents of the systems or ages holding petroleum in the United States, begin with the Pliocene or newest stratified rocks that are capped by the alluvium, followed by the Tertiary, Cretaceous, Jurassic, Triassic, Permian, the upper, middle and lower Carboniferous, Devonian and upper and lower Silurian. That portion lying east of the Mississippi river, and to the northwest of the main uplift of the Appalachian chain of mountains contains the known profitable petroleum fields, which are designated as the Appalachian, and the Lima-Indiana field. The strata containing the petroleum and natural gas in the Appalachian division begin with the upper Carboniferous, and extend downward to the middle Devonian. The probable area of these formations is about 55,000 square miles, extending along a northeast and southwest axis about 700 miles long and 80 miles wide. From this area is obtained the greatest supply of high-grade petroleum. In the States of Kentucky and Tennessee, however, a limited amount is produced from strata much lower in the scale. The central point of this possible productive area is not far from the southwest corner of the State of Pennsylvania, and is distant from New York, by way of the pipe-line route, 520 miles, and from Philadelphia and Baltimore, 380 miles. Near these cities the greater refineries are located, which convert the crude product into illuminating oil and other manufactured products. Two-fifths of the northern portion of this great petroleum area contain the prolific pools of Pennsylvania, New York, West Virginia and southeastern Ohio. The whole of the productive area is covered by a labyrinth of smaller pipe lines connecting over 90,000 wells, which feed the main lines that supply the inland and seaboard refineries. The Appalachian division produces over 60% of the entire output of crude petroleum east of the Mississippi river. The other division of the

productive area east of the Mississippi river, known as the Lima-Indiana field, is on the line of a much more ancient uplift (the Cincinnati arch) than that of the Appalachian field. It starts in Alabama, where the Appalachian uplift and the Cincinnati arch coalesce, as it were. The latter then takes a course a little east of north, passes through Tennessee, Kentucky and northwestern Ohio, crosses over into Ontario, Canada, and curving to the eastward finally terminates in a series of extinct volcanic islands on the east of Hudson Bay. In its southern portions it is a gentle swell without faulting to any great extent, with gentle slopes and undulations along its crest line. North of the Ohio river a branch line of uplift crosses into central Indiana in a general northwestern course. On the crest of the main line of elevation and its branches in Ohio and Indiana the greater supply of gas and petroleum is found, although there are many localities south of the Ohio river which have produced considerable petroleum from the same general topographical and geological conditions. In this last named region the conditions are lacking for the proper accumulation of the liquid and gaseous hydrocarbons.

The production in this area is secured in the Trenton limestone of the lower Silurian or Cambrian division, which is usually several thousand feet below the productive areas of the middle Devonian in the upper Appalachian field. In quality the petroleum produced is inferior to that of the Appalachian field. The yield of the more valuable and volatile products is less, and it contains 0.6% S as hydrogen sulphide, which is difficult to remove in the process of refining. This field produced 21,933,380 bbl. in 1901, which was 40% of the output of the combined Appalachian and the Lima-Indiana fields. This field also is covered by a network of smaller pipe lines connecting many thousand wells with the receiving tanks. A system of trunk lines extends as far as Chicago on the west, while to the east it connects with the other main lines reaching the Atlantic seaboard cities. There must be at least 10,000 miles of trunk line pipe from 4 in. to 8 in. in diameter that convey the crude oil from the various fields to the points of manufacture. These lines are buried from 2 ft. to 3 ft. deep in order to reduce the amount of expansion and contraction. They are constructed of wrought iron and steel lap-welded pipe in lengths of from 18 to 22 ft. On each end sharp threads are cut with a taper from 9 to 10 in., which are screwed into couplings also tapered, to make a complete fit. A large force of men are usually required to "set up" the joints to the proper tension. The trunk line pipe is tested to a pressure of from 1,500 to 2,000 lb. to the square inch.

The distance between pumping stations on the main trunk lines is usually from 28 to 50 miles. These distances can be varied more or less owing to the elevations to be overcome, by the addition of an extra line or a loop from the point of discharge, to such points as are convenient for fuel or water. The pumps employed in the service are of the highest mechanical excellence. They are flywheel-connected, triple-expansion, and built by the National Transit Co., at Oil City, Pa. The pipe line may be compared to the steel rail, and the pump to the locomotive in this method of transportation.

*Performance of Pumping Engines.*—A test was made of one of these pump-

ing engines in 1892 by Prof. J. E. Denton, of Stevens Institute, Hoboken, N. J., at Laketon, Ind., in which Indiana petroleum was used for fuel. The test was made while the engine was performing its regular duty of forcing 30,000 bbl. of petroleum per day through 54 miles of pipe under a pressure of 600 lb. to the sq. in., at 28 revolutions per minute. The efficiency of the mechanism was found to be 94.5%; the diameter of high pressure cylinder was 24.12 in., intermediate 38 in., low cylinder 54.0 in., with Corliiss valves and adjustable cut-offs, length of stroke 36 in., with two single acting air-pumps, condensers, etc. These operated six plungers, 8 in. in diameter, set beyond the main shaft in line with the cylinders. The average horse power exerted on the pump pistons amounted to 300 H.P., with 328 H.P. developed by the steam cylinders, and average boiler pressure 150 lb. The general conclusions arrived at as the result of numerous tests carefully made showed a water consumption of but 13.50 lb. per hour per horse power at 20 expansions, which is very close to the best results of the most improved ocean liners.

*Performance of Boilers.*—The following is the result of the experiments with two boilers at Laketon, Ind., which supplied the steam to the triple expansion engines previously described, the fuel being crude Indiana petroleum, burned with a Cobb & Towl compressed air burner. The boilers were of the horizontal tubular type, 5 ft. in diameter, 14 ft. long, and contained 182 two-inch tubes, with a water heating surface of 1,180 sq. ft. The average evaporation, at 212°F. for 7 tests, was 16.10 lb. of water per lb. of petroleum, corresponding to 15,553 B.T.U. that were effective. The steam was perfectly dry. The average evaporation per hour per sq. ft. of heating surface was 1.9 lb. at 150 lb. gauge pressure, and 60° temperature of feed water. The air was supplied by a Root Blower at the rate of 240 cu. ft. per minute, and at about 0.5 lb. pressure per sq. in. The blower was driven by a small steam engine whose consumption of steam amounted to 1.5% of the steam evaporated by the boiler.

Quite recently Prof. J. E. Denton made a very exhaustive test of the evaporative power of the Beaumont petroleum for the Export Oil & Pipe Line Co. of Beaumont, Texas. One pound of Beaumont oil evaporated 15.1 lb. of water at 212°F., representing 14,587 B.T.U., which demonstrated that the Beaumont petroleum, for fuel purposes, is the equivalent of about 95% of the value of the Indiana crude petroleum. Numerous tests have proven that when the liquid hydrocarbons are sold by the gallon or barrel and not by weight, the calorific value is remarkably close, whether it be residuum of various grades or crude petroleum from California, Texas, Indiana or Pennsylvania.

*Comparative Cost of Coal and Petroleum.*—The equivalents given in the table on the following page are considered to be secured in ordinary practice. Western coal will evaporate 6.5 lb. of water from and at 212°F.; Pittsburg coal, 8.7 lb., and Beaumont petroleum, 13.5 lb., the proportion remaining the same for better or poorer results under boilers.

*Alaska.*—In Alaska there are remarkable surface springs of petroleum, but the climate and physical conditions of the region have for several years baffled the skill of the promoters to test them successfully.

*California.*—Southern California is the present great producing region of

COMPARATIVE COST OF COAL AND PETROLEUM.

| Price of South-western Coal per Ton of 2,000 Lb. | Number of Barrels of Beaumont Petroleum to Equal One Ton of Coal. | Price of Beaumont Petroleum per Barrel to Equal Cost of One Ton of South-western Coal. | Price of Ordinary Pittsburg Coal per Ton of 2,000 Lb. | Number of Barrels of Beaumont Petroleum to equal One Ton of Pittsburg Coal. | Price of Beaumont Petroleum per Barrel to Equal Cost of One Ton of Pittsburg Coal. |
|--------------------------------------------------|-------------------------------------------------------------------|----------------------------------------------------------------------------------------|-------------------------------------------------------|-----------------------------------------------------------------------------|------------------------------------------------------------------------------------|

the Pacific coast, with its most remarkable recent developments of a greatly increased amount of fuel petroleum in a region that is destitute of valuable coal deposits. While nearly all of the fields increased their production during the year 1901, the great increase came from the comparatively recent pools about Bakersfield in Kern County, which are known as Kern, McKittrick, Sunset and Midway pools. A very remarkable increase in production is recorded for these four pools. The production of the group for 1900 was less than 900,000 bbl.; for 1899 it was 15,000, and for 1898 it was 10,000; nothing being recorded for 1897 from this county. The production for 1901 from 447 wells—which was sold at an average of 40c. per bbl.—suddenly increased to 4,500,000 bbl. under adverse conditions of congested railroad transportation and overflowing tanks. Had these been ample the production would have been considerably increased.

The production of the counties of the State for 1900 and 1901 is as follows:—

| County.            | 1900.     | 1901.     |
|--------------------|-----------|-----------|
| Kern.....          | 822,500   | 4,493,455 |
| Los Angeles.....   | 1,370,263 | 2,188,683 |
| Frisco.....        | 532,000   | 790,650   |
| Ventura.....       | 418,000   | 463,127   |
| Orange.....        | 872,200   | 724,565   |
| Santa Barbara..... | 153,750   | 135,900   |
| Santa Clara.....   | 771       | .....     |
| Unapportioned..... | 225,000   | .....     |
| Total.....         | 4,324,484 | 8,786,390 |

The value of the production for 1900 amounted to \$4,078,975, an average of about 94c. per bbl.; that for 1901 amounted to \$4,974,540, or 57c. per bbl. There were a large number of tanks constructed in the Kern river valley to furnish storage for this petroleum by the Pacific Coast Oil Co. Between 30 and 35 of these large tanks were completed during the year 1901, and the number has been considerably increased at this writing. The most important undertaking was the construction of a large refinery at Port Richmond, on the waters of San Pablo Bay, near San Francisco, and its connection with the Bakersfield district in Kern County, 270 miles distant, which will insure an outlet for the petroleum that this field is capable of producing, as well as supplying the section near San Francisco with an abundance of cheap liquid fuel that has already greatly contributed to the prosperity of that city and the surrounding section.

The problem of conveying the heavy petroleum, ranging from 14 to 16°, produced in the Kern river pools—which corresponds to 0.972 and 0.945 sp. gr., weighing on an average of 8 lb. to the gal. when the weight of water is 8.331 lb. to the gal., in an 8-in. line for any distance—is one that has been heretofore unsolved by any pipe transportation company in the United States or elsewhere.

Wells are now being drilled with fair indications in Humboldt County, in the northern portion of California.

*Colorado.*—Colorado has been an important producer of petroleum in what is known as the Florence field since 1887, and has produced a very considerable quantity of petroleum of a very fair quality, which in 1901 amounted to over 460,000 bbl. At Boulder, toward the close of the year, a well on the McKennie farm, after passing through a number of pay streaks at 900, 1,200, and 1,540 ft., at about 2,720 ft. found a pay streak containing a considerable amount of excellent petroleum of a gravity of 42°B. This was followed by numerous other wells, nearly all of which have found more or less petroleum; however the deep wells thus far have found only moderate quantities of this superior petroleum, which has had a rather discouraging effect on the development. A great number of stock companies were formed, and an immense amount of capital invested. Companies commenced to drill along the foot hills of the eastern slope of the Rocky Mountains at Colorado Springs, Golden, Boulder, Fort Collins, and extending to the Wyoming State line. By the latter part of February, 1902, there were 48 wells drilling in the State and 100 rigs built. The greater part was in the region northwest of Denver. The production thus far has been secured from the sandy beds of the upper Cretaceous formation.

*Kansas.*—During 1901 the petroleum field in southeastern Kansas produced 179,150 bbl. of oil, valued at \$154,373, which was an average of 86.2c. per bbl. The production for 1900 was 74,714 bbl., thus showing a gain the past year of 139.78%. The value of the natural gas produced in 1900 was \$356,900, while the total value of all the natural gas in the region west of the Mississippi river amounted to only \$449,847. The value for 1901 will show a material gain over that of 1900. The advantages of natural gas as a source of heat, light and power, fully described elsewhere in this volume, apply with equal force to the gas developed in Kansas, Indian Territory and Oklahoma.

*Texas.*—The great event in this region the past year was the unexpected flow of a solid stream of petroleum 160 ft. in height from a well drilled by Capt. A. F. Lucas and his associates, Mr. J. M. Guffey and Mr. John Galey, 4.5 miles south of Beaumont, in Jefferson County, and only 20 miles from the deep water harbor on the Gulf of Mexico. This wonderful discovery marked the beginning of a new era in the history of our petroleum development and startled the operators in all the important productive areas in the United States and the Old World. It was not until the quality of the petroleum thus developed was proven to be inferior for illuminating and lubricating purposes that their fears commenced to subside. The immediate rush to secure territory in this neighborhood was unprecedented. Many practical operators from other petroleum regions became interested and, after looking over the field and finding it impossible to secure any territory upon terms that were considered favorable, withdrew. Then

followed a swarm of promoters, who promised the land owner almost anything he asked, or took options on the land at high prices. In the meantime a vast number of stock companies were formed, many of them controlling but a few acres. The promoters had no trouble to convince other parties with money that the whole plain surrounding the mound known as Spindle Top was saturated with petroleum,—that the available territory reached far back into the interior, and that the wells flowed by hydrostatic pressure. These promoters, assisted by irresponsible newspaper adventurers, disposed of vast quantities of stock which had little or nothing to represent it. If there had been such a quantity of petroleum so easily secured, it would have had little value. Thus far it has been possible to sell only a portion of the petroleum that has been produced, and the portion unsold is now tanked at Spindle Top. A few months of reckless drilling sufficed to make it evident that the production was confined to an elliptical area 3,500 ft. by about 2,000 ft. in dimensions, embracing about 170 acres of land on the elevation known locally as Spindle Top, because of its peculiar shape. By the close of 1901 there were 138 producing wells drilled upon this elevation, 55 of which ranged from 75,000 bbl. to 1,000 bbl. per day, and which belonged to companies that could market their oil. The remaining 77 were not producers to any extent owing to the fact that no market could be found for their petroleum, although some were practically dry or very small wells. In addition to these 138 wells there were 28 others that had been drilled, and were known to contain no oil. The production to the close of 1901 will approximate closely as follows:—

PRODUCTION AT SPINDLE TOP, TEXAS, DURING 1901.

|                                                | Barrels.  |
|------------------------------------------------|-----------|
| Produced and sold.....                         | 3,598,118 |
| Stock on hand.....                             | 1,592,770 |
| Estimated loss by conflagration and waste..... | 775,000   |
| Total production.....                          | 5,960,883 |

The petroleum sold and tanked therefore amounts to 5,185,883 bbl., which, at 18c. per bbl., amounts to \$933,459. The outlay in the field, not including the amounts paid for real estate, from January 10, 1901, to the close of the year, has been carefully estimated by Mr. L. C. Sands, of the Oil Well Supply Co., as follows:—

|                                                               |             |
|---------------------------------------------------------------|-------------|
| 138 producing wells at \$7,439 each complete.....             | \$1,035,302 |
| 46 drilling wells at \$4,000 each.....                        | 184,000     |
| 28 abandoned wells at \$15,611 each.....                      | 437,108     |
| 2,895,800 barrels iron tanks at 25c. per barrel.....          | 706,450     |
| 33,150 wooden tanks at 37½c. per barrel.....                  | 12,435      |
| 904,500 barrels iron tanks building at 12½c.....              | 112,000     |
| 190,000 barrels earthen reservoirs at 7½c. per barrel.....    | 18,750      |
| 10 pump stations, average \$7,770 each.....                   | 77,700      |
| 126 miles of pipe, from 10-in. to 4-in., and laying same..... | 560,200     |
| 161 loading racks for 161 cars at \$22.30 each.....           | 18,250      |
| 336 tank cars purchased by oil companies at \$40 each.....    | 260,000     |
| 3 refineries, in process of erection at Port Arthur.....      | 265,000     |
| 84 rotary drilling outfits at \$3,500 each.....               | 294,000     |
| Total amount invested to January 1, 1902.....                 | \$3,951,065 |

From the above figures it appears that the capital expended in this field has been \$4.23 for every barrel of oil produced in 1901. The above figures do not include the immense prices paid for lands upon which these wells are located.

In many instances small parcels were disposed of at the rate of \$120,000 an acre. It is also impossible to estimate the amount paid by the small investors for stock in worthless oil companies. The depth of the wells are less toward the center of the mound, where some found the pay streak at about 900 ft. Those along the edges of the productive area are usually deeper, one finding the pay streak as low as 1,190 ft. Away from this mound wells have been drilled from 2,200 ft. to 2,600 ft. in depth that have not encountered the limestone with more or less free sulphur that is saturated with petroleum and natural gas inside the magic circle. The formation seems to vary as the drillers report it from 25 to 85 ft., or even more, in thickness.

The following analysis of this rock, taken from the Texas Geological Survey, was made by Mr. S. H. Worrell, of the University of Texas:  $\text{CaO}$ , 54.89%;  $\text{CO}_2$ , 42.45%; S (free and in organic combustion), 1.58%; S (as  $\text{H}_2\text{SO}_4$  in combustion), 0.21%;  $\text{Fe}_2\text{O}_3$  and  $\text{Al}_2\text{O}_3$ , 0.50%;  $\text{MgO}$ , trace.

Some samples carry a much larger proportion of free sulphur than is shown in the above analysis. The sand immediately above the cap rock contains pure sulphur crystals as large as hazel nuts. Above the cap rock are a series of loose and compact sands, with considerable iron pyrites in small crystals. There are also irregular beds of clay with an occasional bed of coarse gravel followed by an irregular sandstone which in some instances has contained considerable reservoirs of natural gas. There are other elevations in this portion of Texas from 10 to 60 miles southwest of the one at Spindle Top that have indications of petroleum accompanied in some instances with big flows of natural gas. The condition of the mass of cap rock holding the petroleum in this field is a special one, and is limited to the area as now defined. The floor of the new strata has been disturbed by the intrusion of the older ones in a number of localities in Texas and Louisiana, accompanied by thermal springs, which have carried in solution large deposits of salt, lime, and magnesia. In some instances these mounds have approached the condition of incipient volcanoes from which sublimed sulphur has found its way to the surface, sometimes pure, in other instances as iron pyrite. The temperature of the petroleum at Beaumont is between 80 and 83°F.

Two hundred miles northwest of Beaumont the Corsicana field is located, which for several years has produced a very remarkable petroleum. In 1901 it amounted to about 800,000 bbl. of a remarkably high-grade petroleum, very similar to the better grades found in Roumania and Galicia in Europe. A modern refinery here transforms this product into the higher grades of illuminating and lubricating products.

At Sour Lake, 20 miles northwest of Beaumont, at about 900 ft. depth, salt and sulphur water was encountered which made temporary flows in considerable volume at a temperature of over 100°F. At Sour Lake and at Jennings several wells have encountered large deposits of petroleum in loose sand. At the former locality this deposit was encountered at 680 ft., and in the latter at over 1,800 ft. The loose sand bridges over and retards the flow until it is removed by the drill when the well is usually ready to spout again. These difficulties will gradually be overcome by experience and wells of larger diameter, as similar difficulties have been overcome in Russia and Roumania. In the former country great

quantities of loose sand are vomited out with the petroleum in the flowing wells, or if bailed too deep the loose sand fills up the well and must be patiently removed before it will produce again. About 12 miles northwest of Sour Lake, at Saratoga, two wells have lately produced considerable petroleum of heavy gravity.

There are a great many localities in this State where surface indications of petroleum, natural gas and bitumen have been reported, and probably many more exist that have never been reported. The following is a list of the counties in southeast Texas in which indications of petroleum are said to exist, either as oil or gas flows or solid bitumen: Martin, Washington, Harrison, Trinity, Smith, Anderson, Houston, Nacogdoches, Shelby, San Augustine, Tyler, Jasper, Hardin, Jefferson, Chambers, Brazos, Harris, Grimes, Limestone, Bastrop, Colorado, Caldwell, Atascosa, Duval, Uvalde, Webb, Starr, and Hidalgo; also Pecos, Reeves, and El Paso, in the extreme western portion of the State. Over the great area of this State the future will determine many profitable pools.

*Wyoming.*—There are many pools in this State which are known to contain petroleum in quantity in a range of strata that begins with the Carboniferous and extends up to the Laramine. Numerous wells scattered over a large portion of the State have proven the existence of the article in quantity, but their isolated locations have prevented the marketing of their products. But one pool is operated in Wyoming, that is known as the Salt Creek Pool, 50 miles north of Casper, which produces a remarkably pure lubricating petroleum—the production being about 5,000 bbl. annually, valued at from \$6 to \$7 per bbl.

*Washington and Oregon.*—Wells are now being drilled in these States, with fair indications.

#### WESTERN OIL AND GAS PRODUCTION.

A remarkable increase in the production of petroleum has been recorded during the past five years in the vast region west of the Mississippi river. Oil has been discovered in several of the Rocky Mountain States, and there is every indication that a considerable portion of the world's future supply of petroleum will be derived from these sources. In 1896 only 2.85% of the total production of the United States was found west of the Mississippi. In 1897 the proportion increased to 4%; in 1898 to 6%; in 1899 to 6.5%; in 1900 to 8.5%, and in 1901 to 20%. And there is every indication that 1902 will witness a gain of 33% over 1901. The quantity produced in this section in 1901 was 13,847,792 bbl., while the estimated production for 1902 is placed at 25,000,000 bbl. These figures indicate with what strides the production of the West is overtaking that of the East.

The petroleum produced in southeastern Kansas is from strata that represent the equivalent of the lower Coal Measures of the Appalachian region immediately above the Sub-carboniferous limestone, which would bring it to correspond with the salt sand and "Big Injun" production in West Virginia. This same formation continues on a southwest course through western Indian Territory into the northeastern portion of Texas with increasing thickness of the measures in this direction. The production from this section comes from the oldest strata so far developed in the region west of the Mississippi river; all the other measures so far producing petroleum in this region are of a later formation.

PRODUCTION FOR 1901 BY STATES EAST AND WEST OF THE MISSISSIPPI RIVER.  
(IN BARRELS.)

| East of the Mississippi River. |              | West of the Mississippi River. |             |
|--------------------------------|--------------|--------------------------------|-------------|
| Ohio.....                      | 21,648,000   | California.....                | 8,788,330   |
| Pennsylvania.....              | 12,625,400   | Texas.....                     | 4,308,000   |
| West Virginia.....             | 14,177,100   | Colorado.....                  | 400,000     |
| Indiana.....                   | 5,757,080    | Kansas.....                    | 179,150     |
| New York.....                  | 1,266,600    | Wyoming.....                   | 5,400       |
| Kentucky and Tennessee.....    | 187,800      | Indian Territory {             | 9,000       |
| Illinois and Michigan.....     | 3,000        | and Missouri.. }               |             |
| Total.....                     | 55,554,780   | Total.....                     | 13,684,380  |
| Valued at.....                 | \$59,534,735 | Valued at.....                 | \$4,692,000 |

From the figures in the above table it will be seen that 20% of the total production of the United States came from west of the Mississippi river in 1901, the value of which was not quite 10%, as compared with 80% in quantity and about 90% in value produced east of that river.

The great inland section of northwestern Texas and New Mexico, reaching up to the Canadian border and beyond into the great valley of the Athabasca and Mackenzie rivers, affords great diversity of conditions of geological and structural possibilities that have not as yet been sufficiently examined. The great mountainous region in Colorado, Utah, Wyoming, and Montana, with cross ranges, bringing up the older igneous rocks on whose flanks repose the more recent measures,—which in many instances have indications of petroleum,—have only in a few instances been tested.

### THE PRODUCTION OF PETROLEUM IN FOREIGN COUNTRIES DURING 1901.

BY PAUL DVORKOVITZ.

#### INTRODUCTORY.

AMONG foreign countries exploiting petroleum Russia, of course, stands foremost, and in regard to the development of the Russian fields there is not much to be said. The area has been somewhat extended, and the various outlying districts have been exploited with no specially remarkable results. The gradual change which has been coming over the Russian industry still continues and spouters are becoming a greater rarity, while the pumping wells are supplying a larger proportion of the output from approximately the same average depths as in the year 1900. During 1901 the crisis which had occurred in the previous year was gradually being overcome and although prices have not yet reached the high figure which prevailed two or three years ago the condition of the industry has become much firmer and trading conditions for the next year will, no doubt, prove more profitable to the operators.

One of the chief features in connection with the English companies working land in Russia has been the endeavor on the part of the Russian Petroleum & Liquid Fuel Co., which up to the present time has been the most prosperous, to bring about an amalgamation with the Baku Petroleum Co. The storm which these proposals raised among the shareholders of the former company will be

ll remembered. So controversial was the character of the meeting at which the proposals were presented that the matter was altogether dropped. It may as well to state that the chief object of the Russian Fuel Co. was to obtain a larger area of petroleum land to supplement their own small, but at present very prolific, property.

As far as the trade in other and more distant countries is concerned there is little to chronicle—no great development has occurred, but the industry as a whole in the Far East has made moderate progress. If there has been any special expansion at all it must be looked for in the direction of the use of liquid fuel and in handling and transporting the oil. Chief among the advances which have been made in the use of liquid fuel, stands the voyage of the Shell tank steamer "Lam." This vessel had been run for two years on petroleum, during which time it traversed 85,000 miles and the experience gained on this ship confirmed the previous claims which had been made for the use of the liquid form of fuel. In the early days of the carrying of oil in bulk, it was thought that so large a quantity as 4,500 tons of oil could not be carried in this manner, an idea which has since been successfully confuted by Sir Marcus Samuel and now, there are tank steamers belonging to the Shell Transport & Trading Co. capable of conveying 9,000 tons while four additional steamers are to be added to this fleet, giving a carrying capacity of 11,000 tons each.

Other steamship companies have followed in the steps of the pioneer company and now the North German-Lloyd, the Hamburg-American, the East Asiatic and the China Mutual companies are numbered among the users of this fuel. The Shell Transport & Trading Co. has launched several new large tank steamers which have been used for the extension of the company's trade with Australia, where it has erected considerable storage accommodation. In this connection it may also be mentioned that the company has also entered into a contract with the Guffey Petroleum Co. of Texas to ship its oil to European markets, and the Borneo fields belonging to the same company have also shown considerable progress during the past year.

A special impetus was given to the scientific study of petroleum at the Petroleum Congress in August, 1900, and since that time various schemes have been formulated, and one at least has been put into practice, while there are also endeavors being made in various countries to provide some means whereby specially trained men can be supplied to the oil fields and refineries. Another outcome of this Congress was the organization of a number of national committees formed for the purpose of centralizing the various developments of the industry in each country. In addition to Great Britain, France, Roumania and the United States have now specially constituted committees for this work.

**SOUTH AMERICA.—Brazil.**—The oil deposits occur chiefly in shales which were reported upon very exhaustively in THE MINERAL INDUSTRY, Vol. IX., to which there is nothing new to add.

**Colombia, Venezuela, etc.**—In these States are surface indications of the existence of oil deposits, but up to the present nothing has been done in the way of systematic exploitation. The native population obtain the oil in a primitive manner and use it mainly for domestic purposes. The Venezuelan oil is very

dark in color and has a sp. gr. of 0.95. Ecuador is also reported to possess a rich petroliferous region near Santa Elena, though it has not yet been exploited. The oil is very heavy having a sp. gr. varying from 0.97 to 0.985.

*Peru.*—The development of the petroleum industry, chiefly in the Province of Piura, has not made much headway during 1901, although work is being carried on in various districts. Geologically, the district is chiefly Tertiary and closely resembles the Californian oil belt. The Faustino Piaggio Petroleum Co. has operated a number of wells near Zorritos, two of which yielded 75,000 bbl. per annum. The oil obtained is dark brown in color, with a sp. gr. of from 0.81 to 0.84, and yielded kerosene and lubricating oils. There is also a heavier petroleum with a sp. gr. of 0.94 produced in this neighborhood in small quantities. The Pacific Petroleum Co. has a large tract of land in which about 60 wells have been sunk, yielding about 1,000 bbl. weekly. The average depth of the wells is 500 ft. and it is reported that few if any have turned out dry. The petroleum is brown in color with a sp. gr. varying from 0.834 to 0.848. It yields approximately 30% of kerosene, 10% benzine and 50% of fuel oil. In addition a French company has been working here for several years past producing about 150 bbl. a week from a dozen or so wells.

EUROPE, ASIA AND AFRICA.—*Algeria.*—Although the oil deposits of Algeria have been very extensively investigated, little practical work has been done up to the present time. One or two companies have been formed for the working of the deposits but merely preliminary steps have been taken for the sinking of wells.

*Austria-Hungary.*—The Galician oil industry occupies a very unsatisfactory position in the oil-producing countries of Europe. It has one of the largest oil-producing areas in the world, which will probably be largely developed in the near future. The production of oil in Russia and Roumania must necessarily hamper the development of the Galician industry and internal factors have also hindered its progress. In 1900, according to the official report of the Chamber of Trade and Commerce of Vienna, unfavorable conditions prevailed for the Austrian industry. The question of tariff and freight charges in that year were not at all favorable for the home industry and so far as the output went, the district of Schodnica, which had been regarded as the most important oil-producing field, retrograded, while the districts of Urycz and Boryslaw showed some advance. The producers of Galicia have had to realize that they were not able to supply sufficient crude oil to meet the home demands, and the consequence was that oil was obtained from Russia and Roumania. The paraffine industry, however, has shown more vitality and a greater advance, although even here the imports have been large. The kerosene industry has made but little progress, both Germany and Russia having endeavored to exclude Austrian competition by levying high duties. In addition, the German method of testing kerosene for its paraffine contents has not been favorable to the interests of Galician producers. There is however a movement in progress for connecting the Galician water-ways with the German canal system, via Oderburg, which will bring Galician exporters into touch with the East Prussian provinces of Silesia, Posen, Brandenburg and Pomerania.

One of the chief features of the year was the drilling of a spouter near Kasmachz in the Kossova district. The chief center of boring, however, has been at Boryslaw, where many wells have been sunk to the deeper horizons yielding a regular flow of from 2 to 3 tank wagons daily. One of them, drilled by the Karpathen Actiengesellschaft, produced 5 tank wagons per day.

At the present writing no figures are available to show the movement of the Galician industry in 1901, but in some directions a slight progress has been made. Statistics for the year 1900 are as follows:—

|                     | Production.  | Shipments.   | Pipe Lines. |            | Reservoirs. |                       | Borings and Hand-Dug Wells. |          |            |       |
|---------------------|--------------|--------------|-------------|------------|-------------|-----------------------|-----------------------------|----------|------------|-------|
|                     | Metric Tons. | Metric Tons. | No.         | Length Km. | No.         | Total Capacity. Tons. | Hand-Dug.                   | Borings. |            |       |
|                     |              |              |             |            |             |                       |                             | Drilled. | Exploited. | Total |
| Stanislaw District  | 11,244       | 13,230       | 9           | 17.5       | 190         | 45,000                | 22                          | 20       | 181        | 151   |
| Drohobycz.....      | 221,696      | 224,990      | 10          | 94         | 763         | 115,200               | 92                          | 151      | 751        | 904   |
| Jasio.....          | 98,394       | 118,440      | 18          | 95         | 698         | 75,600                | 108                         | 111      | 718        | 824   |
| Krakau (Rabka)..... |              |              |             |            |             |                       | 1                           | 1        |            | 1     |
| Totals.....         | 336,334      | 356,660      | 35          | 205.5      | 1,650       | 195,300               | 233                         | 286      | 1,596      | 1,980 |

Production, in tons, for the last five years.

|           |         |           |         |           |         |
|-----------|---------|-----------|---------|-----------|---------|
| 1896..... | 339,755 | 1898..... | 323,146 | 1900..... | 336,344 |
| 1897..... | 309,695 | 1899..... | 321,680 |           |         |

With the exception of Protok oil, all Galician crude oils contain paraffine, in amount varying from 3 to 7%. The residue left after distilling benzine and burning oil, is used for the manufacture of lubricating oil and yields paraffine. The lubricating oils contain paraffine and in addition to an inferior appearance, they apparently possess higher viscosity, which, however, does not add to the lubricating quality; as a result consumers now ask for lubricating oils free from paraffine. In the crude oil the paraffine is present in the form of proto-paraffine and ozokerite, which assumes a crystallized form only by distillation.

A modern refinery in Galicia consists of an oil reservoir, a crystallizing vessel, an ice-making machine, a filter press, an hydraulic cold press, a paraffine refining plant and a paraffine filtering plant. The oil reservoirs have a closed steam coil inside to warm the oil in order to remove the water. Should the oil contain water when admitted into the crystallization chamber ice will be formed, producing a stoppage of the filter presses, as well as a breakage of plates. An attempt was made to refine the oil before separating the paraffine, but the oils became dark in color, and required a second refining.

The crystallizing chamber consists of vessels with double linings. Three refrigerating machines are used: the ammonia machine (Linde), the sulphuric acid machine (Pictet), and the carbonic acid machine.

*Dutch East Indies.*—The Royal Dutch Petroleum Co. in Sumatra produced 2,350,000 cases of kerosene during the first nine months of 1901 compared with 900,000 cases during the same period of 1900, and the total production for 1901 will probably exceed 3,000,000 cases. The Moeara Enim Co. also produced a considerable excess over the previous year's output, the total amounting to approximately 2,000,000 cases. The Babat field, from which good results were expected, has proved very disappointing. The Sumatra Palembang Co., which produced 747,000 cases during 11 months of 1900, will probably equal this out-

put for 1901. Other companies are also at work on this island, chiefly the Mining & Timber Trading Co. in Lower Langkat, whose output for 1901 will, in all probability, exceed 500,000 cases. The Moesi Ilir Co. is erecting a new refinery at Palembang. This company disposes of its paraffine and liquid fuel to the Shell Transport & Trading Co. The total output of the Sumatra wells during the fiscal year 1900-1901 was 169,842,000 liters.

In regard to the working on the Borneo fields great progress has been made during the past year. The area of the property of the Shell Transport & Trading Co. here is about 500 sq. miles, the bulk of this having been ascertained as oil bearing. In 1898 the exports amounted to 6,747 tons; in 1899, 33,711 tons; in 1900, 76,051 tons, and in 1901, to more than 100,000 tons. The average production of crude oil during the first month of 1902 amounted to over 3,000 tons per week. The refinery belonging to this company when fully equipped will be able to deal with 1,000,000 tons of crude oil per year. The company owns 30 ocean-going steamers having a dead weight capacity of 120,000 tons. In addition to this for their large foreign trade it has 31 ocean depots distributed among Egypt, India, China, Japan and Australia, while 11 new installations are in progress. The storage capacity available at the present time amounts to 220,000 tons which is being supplemented by 26,000 tons. Moreover, 320 subsidiary depots are scattered throughout the Eastern Hemisphere.

In Java the Deutsch Petroleum Co. produced during 1901 an average of 140,000 cases monthly compared with 136,000 monthly in the previous year. The Java Petroleum Co. has not been so prosperous during 1901 as previously, when its output amounted to 10,000 cases of kerosene per month. The Java fields are not very attractive to capitalists as, although oil is found in many places and in various quantities, there are no very rich deposits. The figures for the production of 1900 in the different fields were as follows:—

|                                                                          | Cases.    |
|--------------------------------------------------------------------------|-----------|
| Java.....                                                                | 1,687,000 |
| Sumatra, by the three companies.....                                     | 2,945,000 |
| Borneo, about.....                                                       | 700,000   |
| Small refineries in Java and Sumatra, not mentioned in above, about..... | 200,000   |

*Egypt.*—Although the work in this field is not of a very extensive character, prospecting work is still going on, and according to some reports good results are anticipated. The Oil Well Supply Co. of Pittsburg has been putting down several borings at Gebel Zeit on the Gulf of Suez on behalf of the American syndicate. The oil is struck at 2,350 ft. and is said to be of a good quality and, if all reports of the possibilities of the Egyptian petroleum industry may be relied upon, there is an excellent future ahead. In the meantime Roumanian oil is making its way among consumers and during the year 1900, 2,230 tons were discharged at Suez for domestic use.

*Italy.*—During the year 1900 illuminating oils were imported into Italy to the extent of 73,807 quintals. The bulk of this was American, while the proportion of Roumanian oil imported showed a decrease over the previous year. As far as production is concerned progress has been made though not of a very striking character. The places of occurrence and the quality of the oil were dealt with in THE MINERAL INDUSTRY, Vol. IX.

*India.*—The two chief oil-producing centers of India are Burma and Assam. The production has made great progress in recent years, especially since 1898, as shown by the following figures:—

|           | Gallons.   | Value. Rupees. |           | Gallons.   | Value. Rupees. |
|-----------|------------|----------------|-----------|------------|----------------|
| 1890..... | 4,132,000  | 283,173        | 1896..... | 15,044,500 | 1,788,600      |
| 1891..... | 6,554,500  | 363,790        | 1897..... | 19,090,000 | 2,357,800      |
| 1892..... | 8,479,900  | 363,600        | 1898..... | 18,973,800 | 1,018,460      |
| 1893..... | 10,463,900 | 771,100        | 1899..... | 23,534,000 | 1,895,900      |
| 1894..... | 11,452,600 | 1,126,700      | 1900..... | 37,739,200 | 2,331,235      |
| 1895..... | 1,300,300  | 1,539,100      |           |            |                |

*Japan.*—The Japanese oil fields, especially that of Echigo, have made good advance during the year 1901, although the principal districts, Amase and Yamada, have shown some signs of a declining production. The Kitno district has attracted considerable attention and a good supply of oil has been obtained from the wells at the Nagaoha Industrial Co., the wells yielding about 800 bbl. a day. Several other companies also have been working in this field. Altogether it is stated that about 70 concerns of an aggregate capital of 15,729,460 yen are engaged in the exploitation of petroleum lands.

From a consular report which was drawn up on the Japanese industry a number of interesting facts may be gathered. It is pointed out that the oil fields of Hokkaido are attracting a good deal of attention and that a large supply of oil is obtainable therefrom.

The crude oil output from the various Japanese fields from 1890 to 1899 was as follows:—

| Year.     | Output of Crude Oil. | Quantity of Kerosene Produced. | Year.     | Output of Crude Oil. | Quantity of Kerosene Produced. |
|-----------|----------------------|--------------------------------|-----------|----------------------|--------------------------------|
|           | Gallons.             | Gallons.                       |           | Gallons.             | Gallons.                       |
| 1890..... | 2,159,640            | 443,846                        | 1895..... | 5,935,080            | 688,040                        |
| 1891..... | 2,322,525            | 516,576                        | 1896..... | 8,373,480            | 666,643                        |
| 1892..... | 2,606,863            | 533,210                        | 1897..... | 9,179,434            | 1,044,110                      |
| 1893..... | 3,737,536            | 434,357                        | 1898..... | 11,145,457           | 717,101                        |
| 1894..... | 6,033,844            | 566,886                        | 1899..... | 18,833,918           | 1,340,125                      |

In regard to the import trade of petroleum in Japan, the year 1900 in spite of the progress made by the Japanese fields themselves, shows a large increase over the previous year, amounting to 67,842,324 gal. compared with 52,421,837 in 1899. The figures for 1900, however, fall slightly short of that for 1898 when imported kerosene amounted to close to 68,000,000 gal. One of the features of the petroleum industry which has made great progress in Japan during the last few years is that of the importation of lubricating oils; in the year 1900 the total importation amounted to approximately 11,000,000 gal., the bulk of which was shipped from the United States.

The Japanese oil fields were described in detail in THE MINERAL INDUSTRY, CHAPTER IX.

*Persia.*—There are rumors of the formation of a Belgian company for petroleum exploitation in Persia.

The Persian petroliferous region extends along a line N.E. and S.W. from Ahku, on the Turco-Persian frontier, to the eastern side of the Persian gulf. The northern part of this basin has its center at Kasharashirin, near Shahku.

Round this village are numerous pits of a depth of about 32 ft. This deposit is situated on an Eocene axis of sand and marl, and the Kurds exploit it in a most primitive manner, contenting themselves with collecting the oil from the pits every four or five days, an average output of 10 bbl. being collected each time. The petroleum is very liquid and of a greenish color. It is refined on the spot. In the center of the Persian basin, parallel to the Bakhtiari Mountains, is the petroliferous district of Lauriston. This district also belongs to the Eocene formation and is characterized by the same blue clays which are found in Galicia. The petroleum deposits are in the neighborhood of important salt and sulphur deposits. The existence of petroleum is conspicuously shown at Chouster. The oil is of a special quality, being of a yellow color, very clear, almost transparent and of a sp. gr. of 0.773. South of this station and a few kilometers from Ram-Armuz are the natural springs of Chardin, one of which has a regular output of about 22 gal. per day. Natural petroleum springs also exist near the Persian convent of Naumzady, Haf-Cheide. These springs, which have an output of about 1 bbl. per day, produce an oil of a greenish color and of a sp. gr. of 0.927. The southern point of the Persian basin is on the shore of the Persian gulf, Dalike being its most important station. In this district, work has been seriously started, which unfortunately could not be brought to a successful finish owing to the inclemency of the weather in the summer, the bad quality of the water, which corroded the boilers, the high cost of fuel, and especially the pillaging by the neighboring tribes. The Persian Bank Mining Right Corporation, which holds the concession of this property, is under the control of Mr. Kmentt. The workmen brought from Galicia as well as those from Baku were not able to stand the climate. The Dalike petroleum is heavy and bituminous, and, according to Redwood, has a sp. gr. of 1.016. Investigations are to be made shortly near Talish, on the shores of the Caspian Sea, where abundant traces of petroleum exist. Drinkable water and cheap and abundant liquid fuel from Baku are obtainable and the natives are better policed than on the Persian gulf.

*Roumania.*—The petroleum industry of Roumania at the beginning of 1901 attracted a considerable amount of attention chiefly from the fact that the endeavor of the Standard Oil Co. to obtain the monopoly of the Roumanian pipe lines had only just been brought to a conclusion. Without entering into the merits or demerits of this affair, it is sufficient to say that Roumania is undoubtedly in great want of capital for the exploitation of its petroleum fields. A number of companies were formed during 1901, including the Telega Oil Co., of London, operating the Telega district; the Bustenari Poiana Oil Co., at Poiana Verbilau; the Roumanian United Petroleum Co., at Poiana, Baicoi and Provitz, and the Parsani Petroleum Mappij. of Amsterdam, at Recea, near Bustenari. In addition there were also a number of local companies.

The production during 1901 has been larger than that of the preceding year to the extent it is estimated of about 25,000 tons, a large proportion of which was provided by the Steaua Romana Co.

*Russia.*—The year 1901 shows a large increase in the production, as compared

In the previous year, the statistics being respectively 11,475,200 and 9,782,721 metric tons, equivalent to 80,945,247 and 72,018,743 bbl., respectively. The output for 1901 was obtained from the various districts in the following proportions:—

| Field.           | Percentage of Total Production. |       |       |       |       |       |       |       |       |       |       |       |       |
|------------------|---------------------------------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|
|                  | 1899.                           | 1900. | 1901. | 1902. | 1903. | 1904. | 1905. | 1906. | 1907. | 1908. | 1909. | 1900. | 1901. |
| Balakany .....   | 39.5                            | 33.0  | 31.3  | 24.4  | 21.9  | 23.4  | 20.4  | 23.4  | 23.8  | 22.4  | 21.8  | 20.6  | 17.8  |
| Bebe-Aibat ..... | 8.4                             | 7.9   | 8.7   | 11.6  | 14.6  | 11.4  | 12.5  | 18.2  | 14.9  | 19.9  | 15.2  | 18.2  | 19.7  |
| Many .....       |                                 | 0.8   | 4.8   | 14.3  | 22.5  | 20.7  | 22.5  | 20.2  | 22.8  | 20.7  | 17.6  | 18.9  | 18.0  |
| Saboontchi ..... | 51.1                            | 50.3  | 55.2  | 49.7  | 41.0  | 44.5  | 37.6  | 38.2  | 38.5  | 37.0  | 43.8  | 41.4  | 41.9  |

It will be seen from this table that the largest production has again been obtained from the Balakany-Saboontchi district, the production of which was obtained from pumping wells to the extent of approximately 6,000,000 tons and by spouters about 600,000 tons, while the Bebe-Aibat fields supplied approximately 1,500,000 tons by pumping and over 500,000 tons from spouters.

This increased supply has been obtained with but slight increase in the average depth of the wells which is evident from the following table:—

| Field.           | Depth of Wells. |           |           |           |           |           |           |           |
|------------------|-----------------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|
|                  | 1894.           | 1895.     | 1896.     | 1897.     | 1898.     | 1899.     | 1900.     | 1901.     |
| Balakany .....   | Feet. 640       | Feet. 624 | Feet. 701 | Feet. 696 | Feet. 720 | Feet. 795 | Feet. 749 | Feet. 749 |
| Bebe-Aibat ..... | 814             | 1,261     | 1,215     | 1,472     | 1,601     | 1,309     | 1,311     | 1,329     |
| Many .....       | 1,108           | 1,080     | 1,214     | 1,225     | 1,439     | 1,339     | 1,428     | 1,456     |
| Saboontchi ..... | 1,020           | 1,030     | 1,030     | 902       | 966       | 994       | 847       | 980       |

During the greater part of the year the large spouter showed unmistakable signs of disappearing but toward the close there was a revival, more especially the Bebe-Aibat district, which brought the total output from spouting wells the month of November far ahead of any previous figure throughout the year.

The stocks of crude oil at Baku at the close of the year compared with the previous year were:—

|                         | Jan. 1, 1901.      | Jan. 1, 1902.      |
|-------------------------|--------------------|--------------------|
| At the well .....       | 1,068,342 barrels. | 2,058,963 barrels. |
| At the refineries ..... | 4,478,881 barrels. | 6,850,738 barrels. |

The number of wells sunk during the year amounted to 355, compared with 434 in the previous year. In regard to prices during 1901 there have been some considerable fluctuations, marked chiefly by a tendency toward decline. In January the price of kerosene in tank wagons was 20.58 kopecks and April 8.48, and for crude oil at the wells 11.42 kopecks in January and 7 kopecks in April. Residuals stood at 13.58 kopecks in January and 3 kopecks in April. Later, however, the prices began to strengthen slightly, and reached in July 13.75 kopecks for kerosene, and 8.4 kopecks for crude. The price for residuals (not taking into account the slight temporary rise from 2 kopecks in September to 8.19 in October), was continually shrinking during the whole period. The year ended with prices at 7.75@8 kopecks for kerosene, 5@5.5 kopecks for crude, and 6.25 kopecks for residuals.

The monthly prices during 1901 are shown in the subjoined table:—

| Month.          | Refined.                        |                                 | Residuals.<br>Kopecks<br>per Pood. | Crude.<br>Kopecks<br>per Pood. |
|-----------------|---------------------------------|---------------------------------|------------------------------------|--------------------------------|
|                 | Inland.<br>Kopecks<br>per Pood. | Export.<br>Kopecks<br>per Pood. |                                    |                                |
| January .....   | 14·84                           | 20·00                           | 13·09                              | 11·56                          |
| February .....  | 12·75                           | 19·72                           | 13·55                              | 11·41                          |
| March .....     | 9·87                            | 19·00                           | 13·12                              | 10·19                          |
| April .....     | 8·75                            | 13·87                           | 13·75                              | 9·81                           |
| May .....       | 8·70                            | 8·25                            | 11·70                              | 9·50                           |
| June .....      | 7·59                            | 9·72                            | 9·55                               | 8·31                           |
| July .....      | 9·80                            | 12·60                           | 9·67                               | 8·95                           |
| August .....    | 8·12                            | 11·50                           | 7·53                               | 7·12                           |
| September ..... | 7·19                            | 7·85                            | 7·69                               | 7·00                           |
| October .....   | 8·80                            | 10·12                           | 10·09                              | 7·12                           |
| November .....  | 7·87                            | 9·25                            | 8·12                               | 7·28                           |
| December .....  | 7·06                            | 8·09                            | 6·97                               | 6·00                           |

NOTE.—1 kopeck equals \$0·0051; 1 pood equals 36·1132 lb.

As for prices of Russian oil in foreign markets, kerosene moved from 106·6 kopecks in January, in London, to 113 in February and March, when it began to fall until it reached its lowest level, namely, 85·1 in June and July. Then followed a further uninterrupted rise and the year ended with the quotation at 111·75 kopecks per pood.

The fall in the prices of crude oil has had a particularly ruinous effect upon those who did not possess freehold plots of land, or plots leased some years ago, but who are working on the Government lands at Bebe-Aibat leased by auction at extremely high royalties, and which in some cases exceed the price of crude oil at the present time. This brought about an intention to petition the Government to replace the payment per pood by one in the form of a percentage of the production. This is an exceedingly important and complicated matter, and at the time of writing is under the consideration of the Government, the large producers having voted solidly against it, the design being supported only by small producers.

The export of Russian oil to foreign countries has made some progress during the year though the inadequate facilities for transporting the oil from the producing centers has undoubtedly hampered its further expansion and will restrict it until conditions are changed. Organization is still the one great desideratum of the Russian industry. The total exports from Russia (via Batoum and Novorossisk) for 1900 and 1901 were as follows:—

EXPORTS OF PETROLEUM FROM BATOUM. (BARRELS OF 42 GALLONS.)

|           | Crude and<br>Residuum. | Lubricating<br>Oil. | Distillate and<br>Solar. | Refined.  |
|-----------|------------------------|---------------------|--------------------------|-----------|
| 1900..... | 214,016                | 1,006,964           | 643,575                  | 5,493,361 |
| 1901..... | 140,551                | 915,710             | 1,038,867                | 6,814,110 |

Among the few companies formed during the year was the Kerosene & Lubricating Oil Co., capitalized at £500,000. This concern is the English flotation of a company already working in Russia, and is a branch of the Russian Petroleum & Liquid Fuel Co.

The exploitation of new regions has been chiefly directed to the Island of Cheleken, where some promising prospecting work has been actively carried on. The Province of Daghestan has also attracted some attention.

The development of the petroleum industry in Grosny is shown by the following figures: In 1899 the production of crude oil amounted to 25,194,566 poods, in 1900 it reached 30,400,000 poods and the production of 1901 approximates 400,000 poods. The Grosny industry, which is largely influenced by the Baku industry, suffered very keenly from the critical condition of the latter during the year. During the first half of 1901 the Anglo-Russian Maximoff Co. was launched with a capital of £400,000. About 30% of the output of the Grosny fields is taken by the Vladi-Caucasian Railway, and in some quarters it is believed it could establish its own markets in the northern Caucasus and on the north coast of the Caspian Sea as well as in the portion of south Russia.

The three principal English companies operating in Russia made the following outputs in 1901: The Russian Petroleum & Liquid Fuel Co., 33,291,000 poods; the Baku Russian Petroleum Co., 22,594,295 poods, and the European Petroleum Co., 16,532,991 poods.

During the year an oil pipe line from Baku to Batoum was being constructed and it is expected to be completed in about three years. The decision of the Russian capitalists was also a matter of moment as was also the question of reclaiming of 300 dessatines (1 dessatine equals 2.6997 acres) of a narrow strip of sea adjoining Bebe-Aibat.

Among other items which should be referred to is the decease during the year of the inventor of mineral lubricating oils, Victor I. Ragsine; the disastrous fire at Baku, which broke out on the property of the Caspian and Black Sea Petroleum Society, in which 200 lives were lost and a large quantity of oil consumed; and the striking of the large spouter by the Baku Naphtha Co. in November yielding 100 million poods a day which, in consequence of unpreparedness, was the cause of considerable loss instead of a source of profit; and the opening of the Petroleum Institute in London, where a series of lectures on petroleum science and technology is delivered.

## PHOSPHATE ROCK.

THE production of all varieties of phosphate rock in the United States during 1901 amounted to 1,503,623 long tons, valued at \$5,336,403, as compared with 1,527,711 long tons, valued at \$5,375,956, which shows a decrease of 24,088 long tons in quantity and \$39,553 in value from the statistics of the preceding year.

### PRODUCTION OF PHOSPHATE ROCK IN THE UNITED STATES. (a) (IN TONS OF 2,240 LB.)

| Year.     | South Carolina. | Florida. | North Carolina. | Tennessee. | Other States. | Totals.   | Value.      |          |

| 1901..... | 321,181         | 751,996  | b 20,000        | 409,653    | 893           | 1,503,623 | 5,336,403   | 3.55     |

(a) The figures for 1899 are based on railway and export shipments, except those for Tennessee, which were furnished by the Commissioner of Labor and Inspector of Mines. In 1898 and 1897 the statistics were compiled partly from shipments and partly from direct reports of the producers. In 1901 the figures are from the report of the United States Geological Survey, based on marketed product. (b) Low-grade rock not used for fertilizing purposes.

**Prices.**—Prices of Florida high-grade rock in 1901 compare with the lowest on record, notwithstanding the fact that exports were the second largest in the history of the trade. Opening in January at \$7.50@ \$8 per long ton, f. o. b. Fernandina, prices receded later to \$6.50@ \$7, and closed the year at \$7@ \$7.50; making an average for 1901 of \$6.83. Abroad market prices were influenced to some extent by low ocean freight rates. Consequently the c. i. f. quotations were \$12.68@ \$13.07 per long ton in January; \$10.53@ \$10.92 in June, and \$10.53@ \$11.31 in December, making a yearly average of \$11.45. Florida land pebble sold at \$3.85@ \$4 per long ton, f. o. b. Fernandina during most of the year, and closed in December at \$3@ \$3.25. Abroad prices receded from \$9@ \$10.15 in January to \$7@ \$8.40 in December. Florida Peace River phosphate brought \$3@ \$3.50, f. o. b. Fernandina early in the year, then receded to \$2.50@ \$2.75, and closed in December at \$2.25@ \$2.50. Abroad the extreme quotations were \$8.70@ \$6; the higher figure was realized early in the first half-year.

Tennessee high-grade rock was in good request, selling somewhat below the price quoted for Florida rock. The difference is due to the higher percentage of iron and alumina in the Tennessee product. Tennessee export rock sold at \$2.50@\$2.90 f. o. b. Mt. Pleasant in January, \$3.25@\$3.50 in June, and \$3.50 in December, making a yearly average of \$3.33. Abroad the c. i. f. quotations were \$11.31@\$11.70 in January, \$10.14@\$10.53 in June, and \$10.53@\$10.92 at the close in December, making an average for the year of \$10.76. Domestic high-grade rock prices f. o. b. Mt. Pleasant were from 25 to 36c. per ton lower than those quoted on export material, and averaged for the year \$2.97. The 75% grade sold at \$2.50@\$3 f. o. b. Mt. Pleasant, and the 70 and 72% grades at \$2@\$2.75.

South Carolina phosphates are consumed mostly at home, though fairly large quantities have been exported. Crude rock sold at mines at \$3.50@\$4 in January, \$2.50@\$2.75 in June, and \$2.75@\$3.25 in December, making a yearly average of \$3.36. Dried rock brought \$4.50 on vessel, Ashley river, in January, \$3.25 in June, and \$3.25 in December, making an average of \$3.65 for the year. Abroad the c. i. f. prices opened in January at \$7.80 and closed in December at \$5.67@\$6.30, according to destination; the year's average being \$6.88. This phosphate competes with the 58 to 63% Algerian product.

*Shipments.*—The shipments of phosphate rock to foreign and domestic ports are given in the subjoined tables:—

(a) A large proportion of the shipments to Rotterdam is forwarded to the interior of Germany. (b) Included in these shipments are those made to the United States, Australasia, Japan, Spain, and the West Indies. (c) Not reported.

*Imports and Exports.*—The total imports of phosphate rock in 1901 amounted to 174,462 long tons, valued at \$868,973, as compared with 137,086 long tons, valued at \$791,189 in 1900. The total exports of phosphate rock in 1901 amounted to 729,539 long tons, valued at \$5,839,215, as compared with 620,070 long tons, valued at \$5,217,946 in 1900. The exports of Florida high-grade rock were 424,130 long tons in 1901, as against 348,556 long tons in the preceding year.

## PROGRESS IN PHOSPHATE MINING INDUSTRY OF THE UNITED STATES DURING 1901.

BY C. G. MEMMINGER.

**Arkansas.**—Early in 1902 the Arkansas Phosphate Co. was constructing a large fertilizer plant on its property, on the White River Railway, which is also under construction and is being extended to the mines. The company has just commenced mining operations on a 2.5 ft. layer of 75% phosphate rock, running less than 3% in iron and aluminum.

**Florida.**—Florida hard rock shipments for the year were 424,130 long tons and with the exception of two small domestic cargoes, were all foreign. There was an appreciable falling off in the production of hard rock during the year, and stocks carried over at the end of the year were lower than in several years previous. In the preparation of the rock there is a marked tendency toward more careful and thorough methods, which is attained usually by the addition of one or more log washers to the ordinary double log plant; also crushing the rock after drying and subsequent dry screening give marked improved results on certain classes of rock. In fact the necessity for more thorough and careful methods of mining and preparation becomes constantly apparent, especially as the higher grade deposits become exhausted and the handling of more difficult material renders improved methods a necessity. A careful study of the entire hard rock territory makes it very apparent that the more easily mined high-grade deposits are by no means numerous and are rapidly becoming exhausted. The extreme northern section is practically exhausted, and in the extreme southern section of the district a number of deposits have been worked and the output has fallen off to a very marked extent. A positive proof of the growing scarcity of the best class of rock is that deposits are now being opened up and developed having an overburden of 25 to 30 ft. A short time ago deposits of this character were hardly classed as available. Unquestionably there is a marked limit to the supply of high-grade rock.

During the year work has been practically completed at Port Inglis, at the mouth of the Withlacoochee river, to handle this rock. It is an open roadstead, and vessels will have to be loaded by lighters. The success of this enterprise and bearing on the movement and rates are yet to be determined.

There have been several unsuccessful efforts on the part of large producers to form a community of interests, which would undoubtedly be of great value to the miners.

**Land Pebble.**—There was a very marked increase in shipments of this class of rock during the year, 273,594 tons being shipped through Port Tampa; considerable shipments were in addition made to interior points of consumption by rail, of which no records are obtainable. A new plant was under process of construction and the indications are for a still further increase of production during 1902.

The application of electricity for the distribution of power in one of the largest and best appointed plants in the district presents a rather novel feature in this class of mining. The economy of this system is yet to be proven, although it has many admirable features. The question of fuel supply continues to become more serious in this district, as the supply of wood easily available for the plants is fast becoming exhausted. Texas oil will be adopted as fuel by at least one plant, and may in a measure tend to solve this problem, but as the fuel forms a large part of the production cost of this class of rock, price of production must naturally increase with increased fuel cost.

A few new deposits of considerable extent have been developed during the year, and there are now large reserves of this class of rock in this district, especially of grades running from 65 to 67% of bone phosphate and from 3 to 5% of iron and aluminum oxides combined.

**River Pebble.**—The shipments of this class of pebble for the year amounted to 46,813 tons, distributed as follows: Domestic, 28,023; foreign, 18,790 tons. There is nothing of special interest in regard to this class of rock.

**North Carolina.**—The shell rock quarry at Castle Haynes, N. C., has been operated for the past two years, although the city of Wilmington is taking the entire output for macadamizing the streets. The estimated quantity of material produced in 1901 was 20,000 long tons, as compared with 15,000 long tons in 1900. These quantities have not been included in the tables of production of the rock, which is of extremely low grade, is not used for fertilizing purposes.

**Tennessee.**—In the Mount Pleasant district the Tennessee Phosphate Co. has been merged with the Federal Chemical Fertilizer Co. It is to be presumed that this company will consume its own rock output and that but little if any will be available for the market. This company, which was one of the principal producers during 1901, has completed a fertilizer plant on the Nashville, Chattanooga & St. Louis Railroad, 4 miles from Nashville. The buildings cover 100,000 sq. ft. of surface, and have a storage capacity of 30,000 tons. The acid plant is to have the latest improvements, and is to be built so that it can be increased as the demand for fertilizers increases. The fertilizer plant is to be equipped with the latest improved machinery, and embodies some improved

methods of handling the fertilizers. The grounds cover 15 acres, and an extensive trackage system is being installed.

The Virginia-Carolina Chemical Co., already holding large properties in this field, is expected to increase them. The absorption of the mines by the large fertilizer companies, if continued, will result in very little of this class of rock being available for the open market. The limits and possibilities of the Mount Pleasant field are well known, and while there will probably be some extension of the field, the discovery of large bodies of high-grade rock is not probable. Mining of the brown and blue rock in Hickman County continues on a small scale. This rock forms an excellent basis for the manufacture of superphosphates. There are large reserves of this rock in Lewis and Hickman counties, but the best and most available deposits are either controlled or owned by the large fertilizer companies. No development of any extent has been done in the white phosphate deposits of Perry County. There is some mining and reports of new finds in several counties of middle Tennessee, but no deposits of important commercial value have been developed.

*South Carolina.*—The bulk of the land rock deposits is owned by the Virginia-Carolina Chemical Co., and the rock is mined for its own consumption. The Coosaw Co., one of the landmarks in South Carolina river rock phosphate mining, has ceased operation and will dispose of its entire mining plant and retire from the business. There is still some river mining being carried on, but on a restricted scale.

*Summary.*—A special feature of interest to be noted during the year is the marked tendency on part of the larger consumers of crude phosphate to secure their own sources of supply. There is also a marked increase in the number of independent fertilizer factories—independent of the so-called fertilizer trusts. Unquestionably there is a very decided increase in consumption of commercial fertilizers, which is especially noted through the Middle States, where lands formerly very fertile now require to be fertilized. Despite the increase in consumption of fertilizer there has been, without apparent reason, a decline in prices of both Florida high-grade and pebble rock, a condition which is certainly abnormal.

#### PHOSPHATE MINING IN FOREIGN COUNTRIES.

*Algeria.*—Due to the decree of 1898, the combine of all the leading producers now operating the phosphate beds at Tocquville, Ainkissa, Dyr and Kouif practically have control of the phosphate mining in Algeria and it is questioned whether any extension of the business will result under the present conditions. The following companies were operative during 1901: The Constantine Phosphate Co., Le Société des Phosphates, de Tébessá, Le Société Française des Phosphates de Tocquville, Crookstons Bros., Hebre & Girault, Argin Kemna Co., and Société Generale des Mines. The factory erected near Bona has been in operation since 1899, the sulphuric acid used being obtained by the treatment of pyrites from Portugal. The products have been sold mostly in the colony, especially for vineyard culture. The shipments of phosphate from Souk-Ahras during 1901 amounted to 226,690 metric tons, apportioned as follows: Compagnie des Phos

tes du Cyr, 88,440; Mine de Kouif, 103,600; La Société Française des Phosphates de Tocqueville, 32,880; Mine de Aiu Kerma, 1,770 metric tons. The duct from the Kouif mine, operated by the Constantine Phosphate Co., is reported to be of the following composition:  $P_2O_5$  31.52% ( $=Ca_3P_2O_8$  68.71%),  $SiO_2$  8.5%,  $SO_3$  2.78% ( $=CaSO_4$  4.73%),  $CaCO_3$  50.77%,  $MgO$  0.62%,  $Fe_2O_3$  1.85%,  $Al_2O_3$  0.85%, combined  $H_2O$  2.35%, organic matter 2.33%, insoluble 0.38%. The cargoes of phosphate rock from the Kouif mine, operated by the Constantine Phosphate Co., were reported of the following compositions:—

| no.  | Water. | Tribasic Phosphate of Calcium. | Calcium Carbonate. | Silica. | Iron and Aluminum Oxide. | Gangue. | Calcium Sulphate. | Magnesium Oxide. | Organic Material and Alkalies. |

High-grade phosphate rock from the Debba mine, operated by the Société Française des Phosphates de Tébessâ, analyzed  $P_2O_5$  31.3% ( $=Ca_3P_2O_8$  68.27%)  $CaCO_3$  17.34%, while that of the second quality was  $P_2O_5$  28.42% ( $Ca_3P_2O_8$  62.04%) and  $CaCO_3$  19.98%.

**Christmas Island.**—The phosphate deposits are reported to contain 86% calcareous phosphate, and in addition to the 12-in. layer on the surface of the island which alone was worked during 1901, a second deposit occurs from 5 to 6 ft. below the surface. In other places prospect pits 40 ft. deep have failed to find the bottom of the deposit. Mining operations are carried on by 700 Chinese coolies, who load the surface material into small iron trolleys extending in as many directions as desired, which are lowered down the hillside by a wire rope and run on iron rails to the tipping shoot, from whence it is loaded into trucks which are tipped into the lighters of from 0.5 to 0.75 ton capacity. The lighters are loaded to the vessels and unloaded by hand—a laborious and tedious operation. During 1900 and 1901 there were 12,000 tons of phosphate shipped from Christmas Island to Japan, and it was estimated that the total shipments during 1901 aggregated 37,000 tons.

**Egypt.**—A discovery of phosphate rock was reported in the region adjacent to the Jorelan river which it is thought will be developed as soon as better means of transportation are at hand.

**France.**—During 1900 the production of phosphate rock in France, amounting to 187,919 metric tons, was exceeded only by that of the United States, which was 233,476 metric tons. These two countries contributed 80% of the world's output for 1900. The progress in opening up the recently discovered deposits in the Vosges Mountains is briefly summarized as follows: The Saint-Gobain Co. has opened several phosphate quarries in the Artillac Valley, between St. Giron and St. Dizier, where the Devonian schistose deposit of from 2 m. to 12 m. in thickness has been almost entirely replaced by nodules of phosphate rock. The rich deposits of Tarteing Milles and Cazalos are also being developed. The Lyons Co. has built a factory at La Bastide de Seron to treat the product from its mines at Rimont, Las Caleses, and Larblont; other mines will be opened up at the

completion of the Saint Girons a Foix Railway. The phosphates deposits of this region are generally associated with manganese ores; in fact the discovery of the phosphate rock was first made at the manganese mine at Las Caleses. The Signat mines contain a slight proportion of nodular phosphate of 70 to 75% richness in schists which yield from 30 to 35%. The mine is favorably located 4 km. from Marignac station. Several quarries are being operated near Accons, on the right bank of the Gave de Lescum river. The deposit of phosphate varying from 1.5 m. to 7 m. in thickness, is free from nodules, although on the left bank nodules are found. The Pyrenean phosphates may be divided into (1) The Basses Pyrenees group, Valley of Lescum, (2) The Central group, Valleys of Luchon and Oueil, and (3) The Ariege group, Valleys of Estangué, Artillac and Arize. It is expected that at the completion of the Saint Girons a Foix Railroad the Ariege group will contribute largely to the output, and it is estimated that the cost of nodules per ton at Castelnau, Durban or Rimont will not exceed 28 fr. per ton.

*Norway.*—The Dahls mine, near Ödegaarden yielded 1,100 tons of apatite in 1900, and the French company operating in the same district recommenced work toward the end of the year. The price for the best apatite during 1900 averaged \$18 per ton at Norwegian ports.

*Russia.*—Owing to the rapid development of the beet sugar industry there has been a large increase in the consumption of superphosphate as fertilizer. The Russian manufacturers, however, of which there are five at present, are able to supply only a small part of the demand, large amounts being imported each year from Germany and other countries. Phosphate rock is mined in the Province of Podolia, on the Dniester river, but the output is small and is supplemented by imports of rock from the United States.

*South Australia.*—New discoveries of phosphate rock were made in the north-eastern part of Yorke peninsula, about 2.5 miles from the port of Clinton. An analysis of specimens from this locality showed 34.56%  $P_2O_5$ , corresponding to 75.4% tricalcium phosphate.

*Tunis.*—A company has obtained a concession at Metlaoui for 60 years of an area of 193 square miles, and a railway has been constructed from the oasis of Gafsa to the mines, a distance of about 28.5 miles, as well as one to the sea coast. The company pays to the State a royalty of 20c. per ton of phosphate up to a total of \$30,000 per annum, after which the royalty on the next 100,000 tons is diminished by 7c. per ton, with a still further reduction beyond this quantity. There are four principal beds, one of 13 ft. in thickness, the next of 6 ft., and the two lower beds of a thickness from 5 to 6 ft. 6 in. The beds contain from 59 to 61% of tribasic calcic-phosphate. There were 1,300 work-people employed on the mine and railway during 1900. The phosphate f. o. b. mines does not cost more than \$1 per ton. It is stated that providing the annual output is 300,000 tons, the total cost at the port of Sfax of the marketable phosphate will be only \$2 per ton.

## THE PHOSPHATE DEPOSITS OF OCEAN AND PLEASANT ISLANDS, IN THE SOUTH PACIFIC.

BY F. DANVERS POWER.

BANABA, or Paanopa, commonly known as Ocean Island, is classed as one of the Gilbert Group, thus coming under British influence, while Nauru, or Pleasant land, is classed in the Marshall Group, and is under German control.

Ocean Island has an area of 1,389 acres, and, like Pleasant Island, somewhat resembles the shape of a kidney in plan. The nearest land is Pleasant Island, 30 miles distant. Neither of these islands naturally belongs to any group, but together with others are known as the "Line Islands." They are raised coral lands and are surrounded by a nearly level shore reef some 100 yd. wide. At the edge the land drops very steeply below the ocean—about 400 ft. in 170 yd. Ocean Island is surrounded by cliffs of coral rock from 12 to 30 ft. high, which are broken up into pinnacles by two series of gullies about 6 ft. wide; one series as a contour similar to that of the island, while the other, at right angles to the former, corresponds more to the boat passages at the edge of the shore reef. From these cliffs the land gradually rises to a height of 260 ft., the center of the land being practically flat. There is no trace of a lagoon to be seen on the land, and if one formerly existed it must have become subsequently filled up and its rim leveled.

The physical features of Pleasant Island, which has an area of 4,692 acres, are somewhat different from Ocean Island. Inland from the shore reef, which is covered at every high tide by about 4 ft. of water, is a cocoanut belt, averaging 100 yd. wide, which is really a continuation of the shore reef, but at a higher elevation on account of having been covered with coral sand washed upon it in banks during storms. On the island side of the cocoanut belt the ground rises suddenly forming a wall of coral pinnacles similar to those surrounding Ocean Island. At the southwestern end of the island, inside the wall, is an oval-shaped range of hills enclosing a lagoon, and from the south of this range a second range passes around the northeast side of it, joining it again at the north. There are occasional passes through these ranges, and occasional peaks on the higher land up to 220 ft. above the sea level. The ground between the ranges is low, while the lagoon is nearly at the same level as the sea. There are other lower ranges trending across the island inside the wall of pinnacles from northwest to southeast.

Inside the outer wall of both islands is covered with lime phosphate of a remarkably uniform and high grade. There is very little soil and the stripping of a few inches removes practically all the organic matter. The phosphate deposits of these islands are controlled by the Pacific Island Co., of London and Sydney, and the good quality of the phosphate, together with the exceptional facilities for mining this material, gives advantages which enables the company to command the Australasian and New Zealand markets.

The phosphate rock is divided into two kinds, classed for commercial purposes: 1) "alluvial," which is in loose grains 0.3 in. and less in diameter, and (2) "rock," which includes loose pieces over 0.3 in. in diameter, also massive blocks

found *in situ*. The classification is merely one of size and not of origin, which was made for the benefit of buyers, some of whom are not provided with coarse crushing appliances.

Geologically there are four kinds of rock: (1) Primary rock, formed and brought into position by chemical means. (2) Primary alluvial, broken up and deposited in its present position by mechanical means. (3) Secondary rock, and (4) Secondary alluvial. There may be ternary and quaternary rock and alluvial, but it is impossible to determine them. However, the original and secondary forms are of interest, as they prove that the island has been raised at least three times and lowered twice, facts which under the circumstances are not easy to demonstrate by other means.

Years ago when these islands were comparatively barren and probably uninhabited, sea birds undoubtedly used them as breeding and depositing grounds. The fish abounding in the neighborhood of the islands supplied them with food and the excess of phosphorus was passed away with their droppings. The bulk of these droppings is enormous, on islands near the Peruvian coast guano deposits having been found 195 ft. thick. The soluble phosphate was leached out of the guano by rain, sea spray and dew, and coming in contact with the underlying coral rock took up the necessary lime to satisfy it, thus becoming fixed as phosphorite, which then collected in joints and other cavities in the rock. At the present time similar phosphate deposits can be seen either filling the joints completely or in layers on either wall. That it has filled in from above is shown by the stalactitic forms it assumes in certain cavities. To prove that the phosphoric acid acted on the coral rock, some of the buried pinnacles unearthed by mining operations have a jacket of lime phosphate, about 0.5 in. thick, underneath which the coral rock has a smooth surface. The phosphate is also found forming interior casts of shells and corals.

In course of time the island sank slightly, and the coral rock, together with the phosphate, became worn down by wave action. The former being more friable and soluble than the phosphate, was broken up into smaller pieces and removed, while the tougher and comparatively insoluble lime phosphate was concentrated in caves and passages (original or weathered, so common in coral islands) in the form of sand and waterworn pebbles, thus forming the primary alluvial phosphate. As the land rose again the phosphate, which was leached from fresh quantities of guano, filtered through to the spaces occupied by the alluvial phosphate and cemented it into a compact body, forming the secondary rock phosphate. Deposits of this type can be seen filling former cavities and possessing a very pretty pisolitic appearance. Again the land was lowered and the rock subjected to disintegration as before. This time, besides primary alluvial, there resulted some secondary alluvial which was formed by the breaking up and rolling about of the secondary rock phosphate. Waterworn composite pebbles of this nature are to be found in the interior of both islands. In the alluvial phosphate are recognized particles that have been deposited under different conditions, i.e., those deposited in joints and those deposited on the floors of the caves. When consolidated these are often mixed up together in a confusion of shapes and sizes, which indicates that they had been stirred up with considerable force.

The action of the sea seems to have had a greater effect on the disintegration of coral rock than that of atmospheric agencies. The sea has cut back the island while forming the shore reef, as is indicated by the caves hollowed out at the foot of the cliffs by the waves. These caves and other passages, whether formed by the building up or the breaking down of the islands, are important, as they form a lodgment for the alluvial deposits. Inland, at the foot of those pinnacles which appear above the surface very little if any detritus of lime carbonate is to be seen even though the material is dug out at the base. This is so general that the natives invariably used blocks of rock phosphate to build the walls surrounding their different properties. This lack of fragments of limestone mixed with the alluvial phosphate causes the latter to be clean so there is no occasion to wash it. A sharp line of demarcation exists between the rock phosphate and the coral rock. The deepest hole sunk on Ocean Island is 29 ft., which does not penetrate through the deposit. The higher pinnacles are 30 ft. above the ground where the material between them has been washed away. The depth of the deposit in the center of the island is unknown, though the holes sunk in various places are sufficient to show that there are immense available deposits of high-grade phosphate. On the tableland at Ocean Island are several shallow depressions which probably indicate the presence of primary rock phosphate deposited in cavities of the coral rock, the limestone having been dissolved out and probably causing a slight local subsidence; at all events, wherever holes are sunk in these places, cavernous rock phosphate has been found, and in other places natural holes or native wells have shown a similar condition.

The following analysis by Mr. A. E. Stephen, of Sydney, of a 3,000-ton shipment from Ocean Island is a fair average of the material. It is calculated on the dry basis. The moisture naturally varies with the weather, but it is generally dried in the sun to 1%.  $\text{CaO}$  53.83%,  $\text{Fe}_2\text{O}_3$  and  $\text{Al}_2\text{O}_3$  0.46%,  $\text{P}_2\text{O}_5$  40.3% ( $=\text{Ca}_3\text{P}_2\text{O}_8$  87.97%),  $\text{CO}_2$  1.5% ( $=\text{CaCO}_3$  3.41%),  $\text{SiO}_2$  0.06%,  $\text{SO}_3$ ,  $\text{MgO}$ ,  $\text{CaO}$ ,  $\text{Na}_2\text{O}$  1.54%, organic matter and combined water 2.31%, total 100%.

The sulphuric acid varies between 0.5% and 0.75%, the magnesia is about 0.75%, while the silica is between 0.1% and 0.2%. Special picked samples have yielded as high as 93% of tribasic phosphate.

An analysis of Pleasant Island phosphate dried at 100° also made by Mr. Stephen gave:  $\text{CaO}$  52.94%,  $\text{Fe}_2\text{O}_3$  and  $\text{Al}_2\text{O}_3$  0.51%,  $\text{P}_2\text{O}_5$  39.86% ( $=\text{Ca}_3\text{P}_2\text{O}_8$  87.01%),  $\text{CO}_2$  1.5% ( $=\text{CaCO}_3$  3.42%),  $\text{SiO}_2$  0.1%,  $\text{SO}_3$ ,  $\text{MgO}$ ,  $\text{CaO}$ ,  $\text{Na}_2\text{O}$  2.43%, organic matter and combined water 2.66%, total 100%.

As is always the case in phosphate analysis, there is an excess of lime over the acids present that are capable of combining with it. This excess is supposed to be in organic combination.

## PLATINUM AND IRIIDIUM.

THE production of platinum from domestic ores in the United States during 1901 amounted to 1,408 oz., valued at \$27,526, as compared with 400 oz., valued at \$2,500 in 1900. This notable increase in production, however, does not begin to supply the United States' demand, the total domestic output being but a very small proportion of the consumption. The production during 1901 was the largest quantity recorded since 1880, the year in which statistics of platinum produced from domestic ores were first compiled. The next largest output was in 1890, when 600 oz., valued at \$2,500, were produced. In connection with the production of platinum from domestic ores during 1901 there were obtained also 253 oz. of iridium, a metal so closely allied to platinum in its properties that doubtless it has formed from 15 to 25% of the reported platinum production in former years.

The chief sources of the domestic supply of platinum are gold placer deposits in Trinity and Shasta counties, Cal., from which the metal is obtained as a secondary product. Platinum occurs also in many other gold placers of California, as well as in Washington, Oregon, Idaho, Montana, and Alaska, but the deposits have not been sufficiently rich to place the extraction of the metal on a profitable basis.

The most noteworthy feature of the platinum industry in the United States during 1901 was the discovery of the metal in the form of sperrylite in the copper ores of the Rambler mine, near Encampment, Albany County, Wyo. Other metals of the platinum group—osmium, palladium, and iridium—were also present, although they were not distributed uniformly throughout the ore, some samples showing palladium and others platinum only. In most cases, however, all four metals were found. The platinum content of the ore varied from 0.06 oz. to 1.4 oz. per ton, and in a selected sample of covellite ( $\text{CuS}$ ) it was as high as 12 oz. The platinum occurs as sperrylite, and in all probability palladium also will be found as an arsenic compound. As a result of this discovery it is important to examine all copper ores for metals of the platinum group; so far, the residues from the electrolytic process in a few of the largest copper refineries have failed to show the presence of the metal.

Other new discoveries of platinum in place which were reported during 1901 are: In peridotite in the Similkameen district, B. C.; traces in serpentine near Weaverville, and near Junction City, Trinity County, Cal.; near Kirby, Josephine County, Ore., and chalcopyrite containing platinum and nickel has been reported as occurring near Bunkerville, in southeastern Nevada.

Samples of rock submitted for analysis by J. C. Carter, of Leavenworth, Wash., contained 0.375 oz. of platinum metals to the ton, and finer material from the same locality contains 0.5 oz. Pt to the ton of ore.

A new discovery of sperrylite, the platinum arsenide mineral, has been reported in the sands of Cowee Creek, Macon County, N. C., where it occurs in minute quantities, but there has been no authentic record of the occurrence of metallic platinum in the Eastern or Southern States.

It is of interest to note that chromite is nearly always associated with platinum, and occurs in the extensive serpentine formations of many mountain ranges in which streams have their source, and in all deposits containing platinum in place, the metal occurs with chromite disseminated through basic magnesium rock of which serpentine is a common alteration product. It has been forecast as within the range of probability that platinum will be found in place associated with chromite in the basic magnesium rocks of California and Oregon as well as in the basic magnesium rock peridotite of North Carolina, Georgia, Pennsylvania and Maryland, which frequently contains chromite. It is to be hoped that future discoveries of platinum will be made which will tend to alleviate the present threatened dearth of this important metal. Chrome ore deposits also should be examined carefully for platinum, as this mineral occurs to a considerable extent in the American platinum as the mineral is its most common associate. The discovery of a use for the osmium which osmiridium, will greatly benefit the platinum industry of the United States; as in the past this mineral has interfered most seriously with the sale of the crude domestic product. The demand for osmium for the new Auer incandescent electric light makes it almost as desirable as platinum.

The world's annual production of platinum for the past few years has ranged between 160,000 and 170,000 oz., of which, as far as can be ascertained, Russia supplies at least 150,000 oz., the balance being obtained from South America.

*Imports.*—The imports of platinum during 1901 were valued at \$1,673,713, as compared with \$1,728,777 in 1900, which shows how insignificant is the domestic supply of this important metal.

*Market.*—The pure platinum content of platinum sands has ranged during 1901 from \$18 to \$22 per oz. New York quotations for the ingot metal per Troy oz. remained at \$18.20 from the beginning of the year until May 11, thence until the close of the year it ruled at \$20.50, and during October, November, and December the price was from \$20 to \$21 per oz., closing the year at the latter figure. Osmiridium is given at from \$6 to \$10 per oz. The price for hammered platinum in quantity varied from 80c. to 82c. per g. during the year, closing at the higher figure.

*Canada.*—A company was formed early in 1902 to develop the platinum claims of 320 acres on Slate creek, just over the divide of the Similkameen

river, on the Washington side. Operations will also be extended into British Columbia territory. Reported assays of the gravel give a value of 25c. per cu. yd., the precious metal content being 66% gold and 34% platinum. Another deposit of platinum is also reported in Kennedy Mountain, near Princeton. The Government assayer at Vancouver, B. C., reports finding considerable platinum in the gold dust from the Klondike received during 1901. Platinum has also been reported with gold in commercial quantities in a quartz vein on a small island in the Lake of the Woods, some 12 miles from the town of Rat Portage, where a pit has been sunk to sample the deposit.

*Russia.*—The production of platinum in the Urals from 1891 to 1900 is given in the subjoined table:—

| Year.     | Poods. | Oz. Troy. | Year.     | Poods. | Oz. Troy. | Year.     | Poods. | Oz. Troy. |
|-----------|--------|-----------|-----------|--------|-----------|-----------|--------|-----------|
| 1891..... | 258    | 185,874   | 1895..... | 260    | 141,068   | 1899..... | 263    | 191,173   |
| 1892..... | 279    | 146,934   | 1896..... | 301    | 158,520   | 1900..... | 282    | 174,946   |
| 1893..... | 311    | 168,787   | 1897..... | 345    | 181,698   | 1901..... | 280    | 200,200   |
| 1894..... | 318    | 167,478   | 1898..... | 365    | 192,225   |           |        |           |

The new Platinum Industrial Co., which bought up a group of the most productive platinum mines and expected to produce an annual yield of 130 poods, reported only 50 poods in 1900.

*New South Wales.*—The production of platinum in New South Wales in 1900 was 530 oz., valued at £1,007, which was obtained chiefly from the Fifield district, about 322 miles west of Sydney, where it is found associated with gold. A deep alluvial "lead" containing the two metals extends for over a mile, varying in width from 60 to 150 ft. The sinking is from 60 to 70 ft., through loam, with some bands of barren quartz drift. The platinum and gold occur in fairly coarse waterworn grains, which are generally confined to the cavities in the bed-rock, and to the wash-dirt for a few inches above it, the latter containing from 5 to 12 dwt. of platinum and from 1 to 3 dwt. of gold per ton. The yield from 269 loads, taken from a number of claims along the "lead," was at the rate of 6 dwt. 21 gr. of platinum and 1 dwt. 23 gr. of gold per ton.

*Norway.*—An extensive platinum-bearing deposit was discovered during the summer of 1901 in the vicinity of Arendal, and a 10-ton experimental plant was erected to test the commercial value of the ore.

#### TECHNOLOGY.

*Electrodes.*—A new form of platinum electrode has been invented by Heraeus<sup>1</sup> consisting of a thin glass tube closed at the lower end, having a number of platinum wires fused into the walls; the projecting ends of the wires are fused to platinum stripes 0.8 in. wide and 0.0003 in. thick, and the inner ends are soldered to an equal number of copper wires attached to a copper block for the electrical connection; 100 g. platinum suffices for 10.75 sq. ft. electrode surface. It is claimed that this new form of electrode can compete in cheapness with carbon.

Heraeus<sup>2</sup> tested platinum-iridium electrodes for chemical restivity in electrolysis alkaline chlorides, and found that with an alloy of platinum of

<sup>1</sup> *Elektrochemie*, September, 1901.

<sup>2</sup> *Zeitschrift fuer Elektrochemie*, March 6, 1902.

6 to 15% iridium, an electrode could be rolled to a thickness of 0.007 mm. and have sufficient chemical resistivity to be used on an industrial scale.

*Recovery from Waste Solutions.*—Adolf Berthold<sup>3</sup> proposes the following for the recovery of platinum from waste solutions. The solution holding platinum salts is first filtered to remove any platinum sponge that may have formed, the latter being dissolved in aqua regia and the solution boiled to nitric acid. The two solutions are then combined and barium chloride added to remove sulphuric acid, after which the platinum salts may be reduced by boiling with concentrated hydrochloric acid and metallic zinc. If a precipitate of potassium-platinic chloride should form during the reduction process, the solution must be heated and any alcohol or ether present driven off. The platinum sponge is removed by decantation and subjected to boiling with hydrochloric acid and to repeated washings with water until all traces of chlorine are removed. A final filtration through a Gooch crucible is to be recommended. In place of the zinc precipitation method, the author believes that the recovery may be effected satisfactorily by electrolysis.

*Optical Determination of Platinum and Iridium.*—Leidié and Quennessen<sup>4</sup> determine platinum and iridium in platinum ores by repeatedly extracting 5 g. of sample with hot aqua regia until complete solution. The united extracts are evaporated to dryness at 105 to 110°C., and the residue taken up with a little water and filtered. The filtrate is heated to 70°C., sodium nitrite is added until the solution is neutral to turmeric, then sodium carbonate to complete precipitation. The liquid is then heated to the boiling point, and filtered to separate the platinum metals from metals of the platinum group. The filtrate is rendered alkaline with NaOH and Cl<sub>2</sub> passed through at a temperature of from 70 to 80°C. to expel as osmium and ruthenium volatile peroxides. The liquid is now acidified with HCl, and more NaNO<sub>2</sub> added to reconvert into nitrites any chlorides of the other metals. In addition to the alkali salts there will now only remain the double nitrites of sodium with platinum, palladium, iridium, and rhodium.

To determine the platinum from 30 to 35% KCl is added, which precipitates osmium and iridium as double nitrites with potassium. Filter the converted osmium and palladium nitrites into chlorides by means of hydrochloric acid, the mass being finally taken up with boiling water. The solution is boiled to remove a slight excess of formaldehyde, which precipitates the two metals in the metallic form. The precipitate is collected, ignited, reduced in a current of hydrogen, and dissolved in aqua regia. This solution is evaporated, the residue taken up with water and reduced to convert palladic chloride into palladous chloride, the platinum is then precipitated with NH<sub>4</sub>Cl, and determined by the gravimetric methods.

To determine iridium, the liquid from which the osmium and ruthenium have been expelled is divided into two parts, one being reserved for the determination of platinum as described above. In the other the double nitrites of rhodium and iridium are converted into chlorides by means of aqua regia containing a little HNO<sub>3</sub>. The iridium is precipitated by NH<sub>4</sub>Cl in the form of a chloro-

<sup>3</sup> *Schrift fuer Angewandte Chemie*, June 18, 1901.

<sup>4</sup> *Journal Pharm. Chim.*, 1901, 351-355.

iridate, the precipitate washed with a solution of  $\text{NH}_4\text{Cl}$ , ignited, reduced in hydrogen, and weighed as metallic iridium. The iridium could also be precipitated with potassium chloride in the form of the double chloride,  $\text{IrCl}_4 \cdot 2\text{KCl}$ , the addition of a little water accelerating the precipitation. Finally the reduced product is washed with water to remove the  $\text{KCl}$ , and dried at  $115^\circ\text{C}$ . This method gives the available iridium only, or that which is in combination with the platinum or other metals, and so dissolves in aqua regia. Any iridium in the free state or combined with the osmium is insoluble, and remains undetermined in the extracted residue.

H. W. Wiley<sup>6</sup> reduced platinum from the hot aqueous solution of potassium-platinic chloride by the addition of aluminum wire or clippings. Hydrochloric acid is added to aid the settling and to dissolve excess of aluminum; the settled platinum is washed by decantation until the complete removal of chloride, the solution being filtered, if necessary, to regain any platinum suspended therein. The spongy platinum residue is heated with nitric acid to remove any copper present and the remaining platinum block is washed, dissolved in aqua regia, evaporated on steam bath until a portion taken on a glass rod solidifies. Water is then added and the solution re-evaporated until nitrous fumes cease to form on the addition of water. The resultant solution of platinic chloride is then ready to be diluted to required strength.

#### NOTES ON PLATINUM AND ITS ASSOCIATED METALS.

BY JAMES F. KEMP.

THE price of platinum has steadily augmented within recent years until now its quotations exceed those of gold. Special interest therefore is attached to its occurrence in nature and above all to its presence in the situations and associations which have not hitherto attracted all the attention that they have deserved. The properties of platinum are altogether exceptional and render it available for scientific and commercial processes for which there seems to be no suitable substitute. These special uses are likely to increase rather than decrease, and therefore, aside from the fact that manipulation and control of the markets may have in some degree caused the increased price, yet the latter is based in part on the actual demand for the metal.

I became interested in the subject while making investigations for the S. S. White Dental Manufacturing Co., and in association with Mr. Albert W. Johnston, to whom acknowledgments are due for the generous permission to use much of the following information.<sup>1</sup>

Almost all the platinum of commerce is obtained from placers and by hydraulic processes. The metal is generally described as occurring in the native state, but this is only partially true. The richest nugget yet assayed and recorded yielded 86.50% Pt. The greater number range between 85 and 70%, and not a few go lower still. Much the most abundant of the other metals which appear in the nuggets, is iron. When all the available assays are plotted

<sup>6</sup> *Journal of the American Chemical Society*, January, 1907.

<sup>1</sup> A more extended treatment of the subject will be found in *Bulletin 198 of the United States Geological Survey*.

found that iron gradually increases as the platinum percentage falls, until it reaches about 69%. The highest iron percentage of which I know is with 68.8% Pt in a specimen from the Urals. Iron then rapidly decreases with the increase of platinum and with values below 80% Pt, iridium to become very abundant. As a rule the other metals of the platinum group, iridium, rhodium, and palladium are always present. Until the platinum below 60% the iridium seldom reaches 5%; rhodium seldom reaches 4%, palladium is less than 2%. In the curves which I have plotted, however, it seems to be no law governing their relations. The above statements it will be further remarked are based upon analyses of what would be mineralogically described as platinum and do not include the other mineralogical species. As the associated metals just referred to, the nuggets often contain osmium, ruthenium, copper, and sometimes even gold, but the percentages are smaller.

The way of mechanical admixture chromite is the commonest associated mineral, some nuggets showing a large proportion of it. Much more rarely it adheres to the platinum, as do also rarer silicates, such as biotite and zircon. Scales of iridosmine have been obtained by dissolving away the more soluble platinum.

Besides platinum the other minerals which contain the metals of this group are the following: Platinoiridium, palladium, allropalladium, and iridosmine (sometimes called osmiridium). There are two compounds with non-metals, arsenosilite ( $\text{PtAs}_2$ ), and laurite ( $\text{RuS}_2$ ). In laurite a little osmium replaces a part of the ruthenium. Of these minerals only iridosmine and sperrylite are of commercial importance. The former has been vigorously sought in recent years because of its osmium, which is much desired on account of its descent properties. Sperrylite as an associate of the nickel-copper ores at Cobalt, Ont., and in the Rambler copper mine, Wyoming, is of more than purely scientific interest.

In its usual associations platinum is found only with the basic, igneous rocks which are rich in the mineral olivine, or chrysolite. They constitute the group of peridotites and are likewise the home of chromite, the commonest associate of platinum. The peridotites change readily under metamorphosing influences to serpentine, and it is therefore not surprising to find that the platinum can be traceable to this mother rock.

As stated above, the platinum of commerce is still almost exclusively obtained from placers and yet the actual gravels seldom rest upon peridotites. It is necessary to follow the streams to their upper portions, in order to locate the mother-lode; but then, so far as known, the peridotites or their relatives are always involved. In the Tura river region of the western Urals, for example, the bed of placers is Devonian limestone but the source of the platinum is in the peridotites up-stream.

In one of two instances in the Urals and in several cases in the Tulameen district of British Columbia, the platinum has been detected by assay in peridotite or in its derived serpentine, but the amounts have proved to be small, or else the metal has been so irregularly distributed, as not to present

e, barite and quartz,<sup>6</sup> and was considered to be a variety of tetrahedrite. French mining engineer named E. Gueymard identified platinum in a tetrahedrite from the French Alps as early as 1847. The ore occurred in the valley of the Rhone in beds of crystalline limestone, in association with dolomite, quartz and arsenic. The other metals present were copper, antimony, lead, zinc, iron and arsenic. In 100 assays, 20 gave either traces or weighable amounts. Gueymard afterward found platinum in similar associations in several other localities in this same general region, and once in bournonite. His results were confirmed by the best chemists of Paris.<sup>7</sup>

The discovery by F. L. Sperry of a heavy metallic residue in the concentrates of the Vermillion mine, near Sudbury, Ont., and its subsequent identification and description as sperrylite ( $\text{PtAs}_2$ ) by Professors Wells and Penfield,<sup>8</sup> first drew attention to the existence of platinum in connection with the nickel-copper deposits of this region, and although it was first observed in the concentrates of a small mill working for gold, it has since been observed in the base metal ores. Clarke and Catlett<sup>9</sup> subsequently determined platinum in quantities respectively of 2.55 oz., 1.8 oz., and 7 oz. per ton in polydymite from Sudbury. The discovery received attention as a possible by-product in treating the mattes.

The most interesting announcement in this connection which has appeared in the past few years is that of the discovery of platinum in the copper ores of the Cobalt mine, already referred to elsewhere in this section. The ore occurs in metamorphic rocks, and exhibits from the surface downward, the iron cap, the magnetite ores, covellite and finally chalcopyrite. The platinum is especially rich in the covellite. The assays show quantities from 0.06 to 1.4 oz. per ton. A sample of wall-rock which I have examined microscopically and which has yielded identifiable amounts of platinum, proves to be a baked slate or hornstone and doubtless came from the contact of an intrusive rock on slates or shales. The rock contains much pyrites. By panning down the covellite, Professors Wells and Penfield have detected crystals of sperrylite.<sup>10</sup>

These discoveries make it extremely desirable to be on the watch for platinum and its associated metals in copper ores. Comparatively minute quantities may have been overlooked in the past and yet may be profitably saved in modern methods of electrolytic refining, especially while platinum rules at its present high prices. Its occurrence is, however, exceptional, and tests of electrolytic methods in some of our largest copper refineries have failed to show it.

It is likewise important to look for it in deposits of chromite since the latter is its commonest associate. But it is important to appreciate that if platinum should be found not associated with a smelting ore of copper or lead, it will be necessary to recover it by some smelting process or by some method of chemical extraction, or by some other method which does not involve amalgamation.

## POTASSIUM SALTS.

THE world's supply of potassium salts, with the exception of saltpeter, continues to be derived from Germany, where the production is controlled by the Kali-Syndicate which was organized by all the active mines for the protection of common interests and especially to avoid overproduction. The agreement first entered into in 1879 has been renewed and revised from time to time. The last renewal dates from June. 22, 1898, was amended on June 29 of that year, and is to run until December 21, 1901. According to this agreement the marketable products are divided into three classes: (1) Crude salt, that is, potassium and magnesium products direct from the mines, not including boracite; (2) manufactured products, so far as they are prepared in the chemical works connected with the mines; (3) mixed salts, mixtures of crude and prepared salts, for fertilizers.

It is understood that early in 1902 an agreement was made by the Kali-Syndicate to supply the Virginia-Carolina Chemical Co. (and probably the American Agricultural Chemical Co. as well) with potassium salts at more favorable terms than those prevailing in recent years. This community of interests resulted from the purchase or option of independent potassium salt properties in Germany by the American companies. The importance of the consumption of potassium salts in the United States is reflected by the large quantity imported annually from Germany. In 1901 the aggregate imports of potassium salts exceeded 100,000 metric tons.

The Kali-Syndicate by its agreement determines not only the sale and the prices of the different products but it has also decided the exact amount which each mine may contribute to the total output. In this connection the products of the mines are divided into four classes, according to their percentage of potassium, as follows: (1) Products with more than 48%  $K_2O$ , an equivalent of 76.1%  $KCl$  or 88.9%  $K_2SO_4$ . (2) Products with not more than 48%  $K_2O$  nor less than 18%, equivalents of 76.1 to 28.5%  $KCl$  or 88.9 to 33.3%  $K_2SO_4$ . (3) Crude salts (not carnallite) with 12.4 to 18%  $K_2O$ , equivalents of 19.7 to 28.5%  $KCl$  or 23.0 to 33.3%  $K_2SO_4$ . (4) Carnallite salts with less than 12.4%  $K_2O$ . The percentage of potash is made the basis for determining the amount of salts of each kind which any manufacturer may offer for sale, but no restrictions are put on the output of the crude material so long as it does not come into the

**ket.** Class 1 includes mostly refined products; class 2, both refined and le; classes 3 and 4, crude only. A method for separating classes 3 and 4 adopted, and will prevent carnallite salts which contain a high percentage potash being sold under class 3. It is based on the relative solubilities of carnallite and kainite in 96% alcohol, the magnesium chloride in the kainite being insoluble, while it is soluble when occurring in carnallite. Salts which contain more than 6% soluble chlorine are put in class 4.

The quota assigned to each member of the Syndicate for the year 1900 is given in the following table, which also gives their relative importance. The figures in each column represent the contribution of each mining company per 100 metric tons of total output for 1900. Statistics for 1901 are not available at time of publication.

| Name of Mining Companies.                    | Class I. | Class II. | Class III. | Class IV. |

| Total.....                                   | 1,000    | 1,000     | 1,000      | 1,000     |

The works belonging to the Syndicate are supplied with 513 boilers representing 53,250 H.P. and 738 engines of 47,420 H.P. The personnel consists of 1,000 officers and 15,570 laborers.

It is believed that deposits of potassium salts exist in certain localities, and the company has been prospecting for potassium salts in the United States for several years, but so far without success.

**Imports.**—The imports and exports of potassium products of the United States are given in the tables at the end of this volume.

The statistics of the Stassfurt salt industry for the past five years are given in the following tables, which were kindly furnished by the Verkaufssyndikat Kaliwerke, Leopoldshall-Stassfurt, commonly referred to in the trade as the "Kali-Syndicate." Statistics from the beginning of the industry in 1857 to 1905, inclusive, are given in detail in THE MINERAL INDUSTRY, Vol. VIII., pp. 480 and 481.

(a) Quantities containing 33% potash.

## MARKETS IN 1901.

*United States.*—The prices established by the Kali-Syndicate for the year 1902, for New York, Boston, Philadelphia and Baltimore per 100 lb. are as follows: Muriate of potash, 80 to 85%, basis 80%, \$1.80; muriate of potash, minimum, 95%, basis 80%, \$1.83; sulphate of potash, 90%, basis 90%, \$2.08; sulphate of potash, minimum 96%, basis 90%, \$2.11; double manure salt, 48 to 53% basis 48%, \$1.09; manure salt, minimum, 20% potash, 62c. For Norfolk, Va., Charleston, Savannah, Wilmington, N. C., and New Orleans, La., add 35c. to the New York prices for muriate of potash salts, 3c. for sulphate of potash salts and 25c. for double manure salt. For bulk salts on basis of foreign analysis, kainite testing 12.4% potash is quoted for New York at \$8.80 per ton of 2,240 lb., invoice weight at shipping port, or \$9.05 actual weight at receiving port; sylvinite, 38c. per unit of sulphate of potash, invoice weight at shipping port, or 39c. per unit, actual weight at receiving port. Kainite prices for Norfolk, Charleston and other Southern ports are 50c. higher, while sylvinite is 2c. per unit higher for Norfolk, Charleston and other Southern ports. These prices are for not less than 500 tons of bulk salts or 50 tons of concentrated salts, and are based on rail shipment from the mines to the seaport. For rail shipments an additional amount of 40 pfennigs per 100 kg. or 5c. per 100 lb. is required.

*Germany.*—The following prices for the different products in 1900 have been

| % KCl | Marks for<br>80% KCl. (a) | % KCl | Marks for<br>80% KCl. (a) | % KCl      | Marks for<br>80% KCl. (c) |
|-------|---------------------------|-------|---------------------------|------------|---------------------------|
| 80-85 | 14.25                     | 96-95 | 14.55                     | 97-98      | 14.25                     |
| 85-88 | 14.35                     | 95-96 | 14.75                     | 98-100     | 15.15                     |
| 88-90 | 14.45                     | 96-97 | 14.85                     | (b) 98-100 | 15.25                     |

(a) One mark=23.8c. The prices are all based on 80% KCl; the excess is charged for at different rates according to the exact analysis of the material. Thus, 84% KCl would cost 14.25 marks plus 0.7125 marks (KCl at basis of 14.25 marks for 80%), or 14.9625 marks. (b) With not more than 0.5% NaCl.

d by Dr. F. Klockmann. (Prices for 1901 not at hand.) They include and are f. o. b. Stassfurt:—

Potassium Chloride. (Prices per 100 kg. in amounts not less than 50 tons.)

Potassium sulphate (high grade, in any amount).—For minimum of  $\text{K}_2\text{SO}_4$  and maximum of 2.5% Cl, 16.45 marks per 100 kg. 90%; for minimum of 96%  $\text{K}_2\text{SO}_4$  and maximum 1% Cl, 16.85 marks per 100 kg. 90%.

Double sulphate of potassium and magnesium (in any amount).—Containing a minimum of 48%  $\text{K}_2\text{SO}_4$  and a maximum of 2.5% Cl, 8 marks per 100 kg. 48%; crystallized, containing a minimum of 40%  $\text{K}_2\text{SO}_4$  and a maximum of 1% Cl, 6.40 marks per 100 kg. 40%.

Potash fertilizer (exclusive of package in carload lots).—For minimum of pure potash, 3.10 marks per 100 kg.; for minimum of 30% pure potash, 6.40 marks per 100 kg.; for minimum of 40% pure potash, 6.40 marks per 100 kg.

Kieserite, calcined and ground (in any amount).—For a minimum of  $\text{K}_2\text{SO}_4$ , 2.60 marks per 100 kg., and no additional charge for an excess percentage.

Rapid strides made by the potash industry are evident in the statistics of production, according to which the total output of salts in 1861 was 2,293 tons, but in 1900 amounted to over 2,000,000 tons.

#### PROGRESS IN THE CHLORATE AND HYPOCHLORITE INDUSTRIES IN 1901.

By J. B. C. KERSHAW.

Changes.—Little change has occurred during 1901 in the electrolytic chlorate industry. The number of works remains stationary at ten, and the power available for the manufacture in these ten factories lies between 30,000 and 40,000 H.P. Details of the factories for chlorate production are given in Table I.

Very reliable figures for the total output of chlorates in 1901 can be obtained and estimates based on the power available are misleading. Most of the factories engaged in the manufacture of electrolytic chlorates produce other products, and since the fall in the price of potassium chlorate below 3.5d. per lb. of chlorine has been to devote an increasing proportion of the power to the production of perchlorates and persulphates.

For figures for individual works, it is calculated, that about 10,000 tons

potassium and sodium chlorates were produced by electrolysis in 1901, and that the output of the electrolytic works is slowly increasing, at the cost of the works still operating the chemical process. As an example of the relative positions of the two processes in France, the following figures published by Guillet for the year 1899 are instructive: Electrolytic works (2), 3,000 tons; chemical works (2), 850 tons; total, 3,850 tons.

Two companies have increased their production during 1901, the National Electrolytic Co. at Niagara Falls, N. Y., and Messrs. Corbin et Cie. at Chedde, France. The former company is now using 2,000 H.P. in the manufacture, in an improved form of the original Franchot & Gibbs cell. This cell is constructed on the filter press principle, without a diaphragm, and has anodes of thin platinum foil, and cathodes of copper wire. An illustrated description of the cell and process has appeared during 1901.<sup>1</sup> Messrs. Corbin et Cie. at Chedde have increased their production, chiefly by improving the efficiency of the cell process. The details of the improvements are not available for publication, but it is probable that they are based upon the use of potassium or sodium chromate in the electrolyte. A small percentage of this compound has a remarkable and unexplained effect in raising the yield of chlorate. At Chedde the ampere hour efficiency has been raised from 42 to 85% and it is expected shortly to attain a current efficiency of 90% in the cell process. In this way, using the same plant and power, the production has been increased from 2,200 tons in 1899, to 4,500 tons, and the works at Chedde now produce more chlorate than any other factory in the world. A market for this chlorate is found in Germany, Italy, America, and Japan, and large quantities are used in the manufacture of a new explosive called "Cheddite." The chemists of the Société d'Electrochimie, at St. Michel and Vallorbes, where the Gall & Montlaur process is worked, are also reported to have considerably improved the efficiency of the process, but details are lacking.

As regards the theory of electrolytic chlorate production, Brochet has published the results of laboratory investigations,<sup>2</sup> which prove that, in all cases, hypochlorite is an intermediate product. The conversion of this hypochlorite into chlorate is the result of a secondary chemical reaction in the cell, and it is in this conversion that the presence of chromate plays a remarkable rôle. In Brochet's own experiments, the reduction at the cathode was diminished sevenfold, when chromate was added to the electrolyte.

Moody & Tucker also have recently investigated the action of chromates, when used with an electrolyte of calcium chloride, and they find that under standard conditions of work, an efficiency of between 76 and 86 per cent. can be attained, for long periods of electrolytic action.<sup>3</sup> In these experiments, the platinum electrodes were horizontal and spaced 10 cm. apart, a current density of 8 amperes per sq. de. of anode surface was used, and the temperature of the electrolyte was maintained at 80°C. It is hoped that this investigation may lead to the utilization of the waste calcium chloride liquors of the ammonia-soda works.

*Hypochlorites.*—Although the use of hypochlorite solutions produced

<sup>1</sup> *The Electrician*, Dec. 13, 1901.

<sup>2</sup> *Elektrochemische Zeitschrift*, February, 1901.

<sup>3</sup> *Journal of the Society of Chemical Industry*, November, 1900.

electrolysis for bleaching purposes is believed to be extending, little detailed information concerning the progress made in 1901 is available for publication.

The experimental trials which were started at Bradford, England, in 1899, have been suspended, as the results obtained were unsatisfactory. Entirely satisfactory working has followed the introduction of the process elsewhere, and we can only assume that the apparatus used in these experiments at Bradford is defective, or that the men in charge of it were responsible for its failure. Further trials with the electrolytic method of producing bleaching solutions, however likely to be made in the United Kingdom, as the Electric Bleaching Co. with a capital of £15,000 has been registered during 1901, to purchase and work two patents granted to A. Vogelsang, relating to electrolytic hypochlorite cells. The Vogelsang cell as stated in my last report in *THE MINERAL INDUSTRY*, I. IX., is already operating at several bleaching works in Saxony.

With regard to France, it is stated that the obstacle to the extended use of the electrolytic method is the large supply of bleaching powder which can be obtained at unusually low prices by the bleach works. Both France and Germany tribute to this overproduction of bleaching powder, the output of each having been greatly increased in recent years by the erection and operation of so many electrolytic alkali works.

The largest installation of electrolytic hypochlorite cells in France of which definite information has been given, is at the cellulose factory of Corbin et Cie. Lancey. The process and cell used here is patented in the name of Paul Bin, and 700 H.P. is said to be utilized in the production of 1,000 tons of bleached cellulose per annum. The cell is characterized by a large number of secondary platinum electrodes held in ebonite frames, with an external structure of iron. The Hermite cell is reported to be in use at a paper works at Amiens, and at one or two textile bleaching works.

In Germany, a very large number of the textile bleaching factories in Saxony and Bavaria use the new method of preparing the bleaching solutions, and cells patented under the names of Kellner, Vogelsang, and Haas & Oettel, are found at these works. Little new information concerning the progress made in these districts has been published during 1901. Oettel has however given figures regarding the yields obtained with the Haas & Oettel apparatus and has stated that one of these are now in use in various works in Saxony. Replying to criticisms by Engelhardt who had claimed a higher efficiency for the Kellner type of cell,<sup>4</sup> Oettel has shown that at high concentration of the electrolyte, the Haas & Oettel cell is the cheaper to work. For weak solutions the Kellner is the more economical. As regards first cost, the Haas and Oettel apparatus to yield 11.2 active chlorine in 9 hours costs 2,500 m. (\$625), while the Kellner apparatus yields 36.7 kg. chlorine in 9 hours costs 13,000 m. (\$3,250). This difference in cost is due to the fact that in the Kellner apparatus, platinum is used as electrode material; while in the Haas & Oettel cell, specially prepared carbon is employed. When worked out as comparative cost per kilogram of active chlorine, the capital outlay in the latter case must be multiplied by 3.3, and the saving is striking than appears at first sight.

---

<sup>4</sup> *Zeitschrift fuer Elektrochemie*, Jan. 31, 1901.

The depreciation with the Haas & Oettel type of cell is estimated at 10%. The carbon electrodes are said to last half a year with proper use. The latest form of Haas & Oettel cell makes use of the pressure of the liberated hydrogen to circulate the electrolyte. In the Kellner apparatus this work is performed by a small pump.

The only note available relative to the use of electrolytic bleaching methods in Austria or Russia, is that the Kellner cell is employed at wood-pulp factories at Gratwein, and at Hallein, in Austria. At the latter works, 200 H.P. is believed to be used, to prepare the bleaching solution, and 15,000 kg. of bleached pulp are produced per day. The brine after electrolysis is reported to contain 1.2% active chlorine. This factory is owned by the Kellner-Partington Paper Pulp Co., which also controls a similar plant at Sarpsfos in Norway. Very few facts have been published concerning the last-named plant, but it is stated that an 800-H.P. Thury dynamo is installed, and that a 5,000-ampere current is generated at 120 volts' pressure.

At Stjernfors, the Hermite cell is reported to be still in use, in a wood-pulp mill producing 1,750 kg. bleached pulp per day; and at Billingsfors in Sweden, a Schuckert installation is in operation, 390 H.P. being utilized, to produce 14 tons bleached cellulose per day. The electrolyzed solution contains 1.4% active chlorine and the cost is said to amount to 182 kr.<sup>5</sup> (\$18.77) for 820 kg. active chlorine. This total is made up of the following items: Power, 52 kr.; salt, 107 kr.; wages, 7 kr.; depreciation and repairs, 16 kr. This plant started work in July, 1900.<sup>6</sup>

### THE MANUFACTURE OF POTASSIUM CYANIDE.

BY SAMUEL AUCHMUTY TUCKER.

THE growing demand for cyanide has resulted in many new processes being devised for its manufacture, some of which perhaps show more ingenuity than practicability; however, in time it would appear that most of the cyanide will be manufactured by processes other than the older methods of fusion with potash or the working up of by-products from the manufacture of gas.

*The Earliest Synthetical Method.*—In the earliest process for making cyanides—which is still used to a limited extent—potassium carbonate is fused with a mixture of iron borings and nitrogenous organic matter such as hair, horn, dried blood, leather cuttings, and the like, in the proportion of 1.25 parts of the mixture for 1 part of the potash, the iron borings being in the proportion of 6 to 8% of the organic matter.

Iron pans set in a reverberatory furnace are used, the temperature being kept just hot enough to liquefy the potash but not so high that the cyanogen compounds are volatilized. As soon as quiet fusion is maintained the mass which consists of potassium cyanide, carbonate, and sulphide, together with iron sulphide, is broken into lumps and digested in hot water for several hours. During this period cyanide is converted to ferrocyanide by the reaction:—

<sup>5</sup> 1 krone equals 26 8c. United States currency.

<sup>6</sup> *Zeitschrift fuer Elektrochemie*, Sept. 6, 1901.

iebig's explanation of the process was that cyanogen is formed from the C and N of the organic matter, the potash being reduced to metallic potassium, which unites with cyanogen to form KCN, and the sulphur is taken up by the iron. On lixiviation the above reaction takes place with the formation of the ferrocyanide. The chief objections to the process are loss of potash and more particularly of nitrogen, and the product is impure.

*Conversion of Ferrocyanide to the Cyanide of Potassium.*—This result is brought about by fusion of the ferrocyanide in a red-hot iron crucible with anhydrous potassium carbonate in the proportion of 8 parts of the former to 3 of the latter. The reaction is:  $K_4Fe(CN)_6 + K_2CO_3 = Fe + CO_2 + KCNO + 5KCN$ . Fusion of the ferrocyanide alone yields:  $K_4Fe(CN)_6 = 4KCN + FeC_2 + N_2$ , the iron carbide formed sinks to the bottom, but not nearly so perfectly as the metallic iron produced in the first case, and consequently results in a more impure product; besides there is a loss of available carbon and nitrogen. In any case the cyanide is contaminated with cyanate and very largely so unless the air is carefully excluded.

Ferrocyanide may also be converted to cyanide in a state of great purity by means of metallic sodium which is now prepared very cheaply by the Castner and other processes. The ferrocyanide in fusion is subjected to the action of molten sodium, which results in the formation of a mixture of potassium and sodium cyanides if potassium ferrocyanide is employed, or in pure sodium cyanide if the raw material is sodium ferrocyanide. This admixture produces a cyanide which, tested by ordinary methods for cyanide of potassium, would assay over 98%, so enough potassium carbonate is added in the commercial product to raise the assay test to from 98 to 99% pure potassium cyanide. A large part of the potassium cyanide in use is made by this or similar methods. The reaction takes place as follows:  $K_4Fe(CN)_6 + 2Na = 4KCN + 2NaCN + 2Fe$ .

*The Manufacture of Cyanide from Ammonia.*—In experiments made to form cyanides by passing atmospheric nitrogen over red-hot carbon together with potash, it was soon found that if ammonia was used instead of nitrogen the yield was increased. Several patents have been taken out using this source of nitrogen, but Young and Macfarlain<sup>1</sup> found that there was a great advantage in using a combination of carbonic oxide with the ammonia, for which they took out a patent in 1892. They claim to have produced a 70% cyanide working on these conditions, but J. T. Conroy,<sup>2</sup> who repeated their experiments, failed to get more than 10% cyanide, and showed that using ammonia alone resulted in but 4% of it being converted to cyanide. W. Siepermann and others suggested the use of sodium carbonate to be mixed with the potash which renders the charge more manageable.

A plant is now in course of erection at Manchester, England, in which cyanide is to be manufactured by the Grossman process,<sup>3</sup> which depends upon the action of ammonia but has several new features. Ammonia gas is passed over a heated mixture of potassium sulphide, carbon, and sulphur in a suitable retort. Potassium cyanide is the chief product formed, together with a small quantity

<sup>1</sup> English Patent No. 3,092, 1892.

<sup>2</sup> *Journal of the Society of Chemical Industry*, 1896,

<sup>3</sup> United States Patent No. 671,479.

of sulphocyanide, which can be neglected. The retorts are so arranged that the gas may be passed from one to the other, and the mixture is chosen to avoid caking at the temperature employed, *i.e.*, 700 to 800°C. When the reaction is completed the mass is withdrawn and lixiviated, by which means the potassium cyanide is obtained, or by the addition of a suitable iron salt ferrocyanide may be prepared. The process seems to promise well, and its success will probably depend upon how much of the ammonia can be converted to cyanide. One drawback to the use of ammonia is found in the action which always takes place between that gas and metals at high temperatures. It has recently been shown<sup>4</sup> that there is no metal which will withstand its action, and consequently the deterioration of apparatus is likely to be a large item.

Castner<sup>5</sup> took out a patent in 1894 for the manufacture of cyanide by the use of metallic sodium upon hot carbon together with nitrogen, but ammonia was soon substituted for the nitrogen. Vertical iron retorts are used, melted sodium being passed downward over the heated carbon, while anhydrous ammonia is admitted below. The temperature is low (300 to 400°C.) and the reaction taking place is in two stages, as follows:  $\text{NH}_3 + \text{Na} = \text{NaNH}_2 + \text{H}_2$ . Then sodium amide reacts with the carbon producing:  $\text{NaNH}_2 + \text{C} = \text{NaCN} + \text{H}_2$ .

*Cyanide from Sulphocyanides.*—Sulphocyanides may be prepared according to the process of Gelis, which has been modified by Tscherniak and Gunzburg<sup>6</sup> which consists in heating carbon-disulphide and ammonia under pressure. The temperature is 125°C., and the mixture is agitated in an autoclave. The first reaction to take place is the formation of ammonium-di-thiocarbamate:—

which changes to sulphocyanide as follows:  $\text{NH}_4\text{S}_2\text{CNH}_2 = \text{NH}_4\text{SCN}_2 + \text{H}_2\text{S}$ . The hydrogen sulphide exerts an enormous pressure which requires the use of expensive apparatus and this was obviated by Hood and Salamon<sup>7</sup> in 1891, who improved the process by using Weldon manganese residues to absorb the gas, but a still greater advantage was found in the use of slaked lime, for which Hurter<sup>8</sup> and others took out a patent in 1893. The reaction may be expressed as follows:

Conroy obtained a quantitative production working on these lines.

*Conversion of Sulphocyanide to Potassium Cyanide.*—Playfair<sup>9</sup> investigated this question, making numerous experiments with different metals having an affinity for sulphur, and came to the conclusion that zinc was the most efficient. The sulphocyanide is added to the fused zinc and the two thoroughly incorporated, by which means the sulphur is removed as zinc sulphide which may be converted to metallic zinc again or oxidized to sulphate. These results have since been confirmed by Conroy.<sup>10</sup> Another method for the removal of the sulphur

<sup>8</sup> English Patent No. 21,451 of 1893.

<sup>9</sup> *Journal of the Society of Chemical Industry*, 1892, 4.

<sup>10</sup> *Journal of the Society of Chemical Industry*, 1898, 98.

t of Raschen,<sup>11</sup> which depends upon the oxidation of the sulphur. The process is said to be in use in England at the present time. Stated briefly, nitric acid acts upon sodium sulphocyanide oxidizing the sulphur to sulphate, being reduced to nitrogen monoxide which is subsequently oxidized again to nitric by atmospheric oxygen. The reactions taking place are in two separate stages:—

Switt proposed oxidizing the sulphur in solution by means of some suitable oxidizing agent such as permanganate.

*Extraction of Cyanide from Gas Works.*—It has long been known that in the distillation of coal that some of the nitrogen present is converted to cyanogen compounds. In 1845 Bunsen and Playfair investigated the formation of cyanide in a blast furnace, and proposed a method for its manufacture. There is no doubt that considerable cyanide is formed in both the blast furnace and in coking, but up to the present time no economical method has been devised for its extrac-

tion by the destructive distillation of coal for illuminating gas, however, much work has been done dealing with cyanide manufacture. Just how cyanide is found in gas is not quite clear, but the following points are now understood and have been pointed out by H. Poole:<sup>12</sup> (1) Cyanogen is known to be in the crude gas as ferrocyanic acid, ammonium cyanide, and sulphocyanide, but not as ferrocyanide. (2) Prussian blue is found in the purifier under ordinary circumstances in small quantities. (3) Sulphocyanides may form in the purifier when ferrocyanide is present in the gas, and ammonia favors their formation. Ammonium sulphocyanide and potassium ferrocyanide are now prepared in considerable quantities from the spent iron oxide in the purification of illuminating gas. The spent oxide is first treated with water at 60°C., until the solution has a density of 1.07. The solution is then concentrated to 1.2 sp. gr., allowed to crystallize. In this way crude ammonium sulphocyanide is obtained which is purified by recrystallization, and may be converted to cyanide by the methods already pointed out.

Bueb<sup>13</sup> took out a patent in 1898 for improvements in the extraction of cyanides from coal gas, and at present the process appears to be a promising one. It not only aims at the extraction of the cyanide but also lends itself to the purification of the gas, for hydrocyanic acid and cyanogen compounds generally known to corrode the meters or other gas apparatus.

The crude gas is passed into a special washer after it has traversed an ammoniacal spherule condenser and tar extractor, in which is run a solution of ferrous sulphate of 17 to 19°B., arranged to traverse the washer in an opposite direction to that of the gas. The reactions taking place are the following:—

<sup>11</sup> English Patent No. 21,678 of 1895.

<sup>12</sup> *Journal of Gas and Lighting*, 70 [1904], 1234-1236.

<sup>13</sup> English Patent No. 9,075 of 1898.

The product, which is in the form of a thin mud, is then pumped out and contains 6 to 8% ammonia and an equivalent of 20% ferrocyanide of potassium. This is distilled for the ammonia and the residue worked up for Prussian blue and yellow prussiate. The quantity of cyanogen obtained of course varies with the variety of coal employed, but according to Bueb, 7.4 oz. are obtained from 1,000 ft. of gas furnished from English coal and somewhat less with other European coals.

*Cyanides from Atmospheric Nitrogen.*—The formation of cyanogen by combination of heated carbon and the nitrogen of the air is impracticable, not to say impossible, under ordinary conditions. It can, however, be accomplished by the addition of a suitable alkaline earth base, and this was suggested by J. Young,<sup>14</sup> but his process calls for a comparatively low temperature; and what is actually required is the formation of a suitable alkaline earth carbide which requires a high temperature, and then the subsequent transformation of this carbide to cyanide by means of atmospheric nitrogen for which a lower temperature is necessary.

This idea has been successfully carried out by the Bradley-Jacobs patent.<sup>15</sup> The process consists in coking a mixture of barium carbonate and small coal in a retort, which results in a very porous material. This porous mixture is then subjected to a high temperature in a rotary electric furnace, resulting in the formation of a porous carbide of barium. The next step is the addition of nitrogen gas, derived from producer gas or directly from the atmosphere, at a lower temperature, by which means barium cyanide is formed. The barium cyanide is then easily converted to any particular cyanide desired, the process being carried out continuously. Experimentally, the method has succeeded, and it is shortly to be put in operation at Niagara Falls.

Processes of a similar nature have been brought out abroad by Dr. A. Frank in 1895, and by Dzink in 1899, but the first is not a continuous process, and the second does not take advantage of the lower temperature necessary for the formation of cyanide from the carbide. The reactions taking place in the Bradley-Jacobs process are the following:—

<sup>14</sup> English Patent No. 24,856 of 1893.

<sup>15</sup> United States Patents, Nos. 657,937 and 658,696, September, 1900.

## QUICKSILVER.

production of quicksilver in the United States during 1901 amounted to 28,727 flasks, against 27,855 flasks in 1900, due to the development of the Rhodinher electrolytic processes for the manufacture of soda and chlorine which consumed an increased amount.

### PRODUCTION AND EXPORTS OF QUICKSILVER IN THE UNITED STATES.

total production is divided as follows: California, 26,720 flasks; Texas, 2,932 flasks; Oregon, 75 flasks. imports of quicksilver during the past five years were as follows: 1896, \$2,037; 1897, 45,539 lb. 1898, 81 lb. (\$51); 1899, 131 lb. (\$33); 1900, 2,616 lb. (\$1,051); 1901, 1,441 lb. (\$789).

*for*nia.—(By B. M. Newcomb.)—Notwithstanding the increased output of more than 2,000 flasks of quicksilver during 1901, the stock in sight unsold, in New York, January 1, 1902, was but 2,230 flasks. In California no new mines have been added to the list of producers during 1901: the Karl and Bertad, both in San Luis Obispo County. The largest producers were the Rhodinher, of San Benito County; Napa Consolidated, of Napa County; and the Rhodinher, of Santa Clara County, the production of these being about equal. Most of the older producing mines fell off materially in production, which loss was offset by several small prospects outfitted with retorts.

The cost of producing quicksilver from the average California mine fully equipped with modern plant and well developed, will exceed \$35 per flask. Added to this is the cost interest on plant and cost of development work, and the outlook for opening new property is not encouraging. Many mines of the coast are being abandoned at a cost of over \$40 per flask. This heavy cost is largely by reason of the large decrease in the grade of ore encountered in the older properties and by the expense in the newer properties opened up, many of these latter being mines which were idle during the low prices of quicksilver. Modern quicksilver furnaces have reduced the cost of reduction as low as 50c. per ton in one or two plants,

but the average price of reduction of the plants of larger equipment is 65c. to 70c. per ton.

The lowest cost of mining the ore that is reported is an average of \$1.82 per ton. One important producer reports \$2.50 per ton, another \$3.50, and others estimate their cost as high as \$8.50 to \$10 per ton. The cost per lineal foot of development work varies largely also, and is reported from \$2.50 per ft. for the lowest to \$10.50 among the highest for tunnel work. In shaft work and drifting from same, the expense will run higher. The average yield reported comes under 0.6% Hg, the lowest 0.3% Hg, while two important producers and dividend payers report 0.56% Hg. Under very favorable circumstances with a large body of ore a profit can be made on 0.25% Hg at the present price of quicksilver. This grade, however, requires exceptionally good management combined with favorable facilities. The outlook for an increased production of quicksilver is unfavorable. Many of the older producers are falling off in their output and no new mines of importance are being discovered, newspaper reports notwithstanding. One other of the Texas mines has been equipped with a good furnace and may increase the output for a time, provided the California mines keep up their present rate of production; however, the indication is that the Coast production will fall off as much as Texas will increase.

The total production of quicksilver in California in 1901 amounted to 26,729 flasks, against 25,922 flasks in 1900. The price of quicksilver during 1901 in San Francisco ranged from \$46@ \$48 per flask for domestic and \$44@ \$45 for export. London prices fluctuated somewhat during the year, from £9 2s. 6d. to £8 17s. 6d., the average price per flask being lower than in 1900. The Napa Consolidated Quicksilver Mining Co. produced 4,800 flasks, against 4,550 in 1900. The ore mined and treated was 33,930 tons, from which the average yield was 0.54% Hg. The cost of mining, development work and general expense was \$3.94, and the cost of reduction was \$0.66 per ton of ore. The amount of tunnels, drifts, and winzes excavated during the year was 9,488 ft. at a cost of \$2.43 per ft. The Aetna Consolidated Quicksilver Mining Co. neither mined nor treated any ore during the year, the work being confined to opening old and new bodies of ore in the course of which 4,384 ft. of old tunnels and 83 ft. of old winzes were opened at a cost of \$1.05 per ft., besides which 1,995 ft. of new tunnels and drifts were excavated at an average cost per foot of \$4.97, to develop a new ore body discovered from shallow surface working. The company recovered from cleaning the old condensers 228 flasks of quicksilver, which realized \$10,290. The deficit for the year \$18,418, reduced the balance brought forward from the previous year amounting to \$79,129 to \$60,711. The New Idria Quicksilver Mining Co. mined and treated 31,866 tons of ore for a recovery of 4,800 flasks or an average yield of 0.576% Hg. A new furnace was erected and put into operation during the year. The cost of reduction of the ore was \$0.64 per ton. The cost of mining per ton, including development work, was \$1.82, and 1,422 ft. of tunnels, raises and drifts were excavated at a cost per ft. of \$4. The sales of quicksilver realized \$211,484; increase of supplies, \$104; interest, \$416; total, \$212,004. The total expenses were \$155,649, leaving a net balance of \$56,355. Dividends of \$60,000 were paid, leaving a deficit of \$3,645, which being

ated from the reserve of the previous year amounting to \$44,574, left a surplus of \$10,929 carried forward. The Boston Quicksilver Mining Co. mined and sold 19,045 tons of ore for a yield of 1,545 flasks of quicksilver, which was mined at a cost for mining, including development work, of \$2.58 per ton, the cost of reduction amounted to \$0.61 per ton. The amount of tunnels, shafts and winzes excavated was 2,507 ft. at an average cost of \$2.50 per ft. A new furnace was completed and put into service during the year and the old one was closed down for repairs.

## QUICKSILVER PRICES PER FLASK AT SAN FRANCISCO IN 1900 AND 1901.

| th.    | Domestic. |         |          |         | Month.       | Domestic. |         |          |         |

| .....  | 51.50     | 51.50   | 47.00    | 46.50   | September..  | 49.00     | 48.50   | 47.50    | 47.50   |
| .....  | 52.00     | 51.50   | 46.50    | 46.00   | October..... | 48.50     | 47.50   | 47.50    | 47.50   |
| .....  | 51.50     | 51.50   | 47.00    | 46.50   | November...  | 48.50     | 48.00   | 47.50    | 46.50   |
| .....  | 51.00     | 49.50   | 48.00    | 47.00   | December...  | 48.00     | 48.00   | 47.50    | 47.50   |

price of quicksilver for export during 1900 varied from \$47.50 per flask in January to \$45 per flask in December. During 1901 it was practically constant at from \$44 and \$45.

*gon.*—The production of the Blackbutte quicksilver mine in Lane County amounted to 75 flasks during 1901, the small production being due to the difficulty of blocking out greater ore reserves, the furnace being closed the greater part of the year for that purpose.

*as.*—The total production of quicksilver during 1901 was 2,932 flasks, against 750 flasks in 1900. The only producers in 1901 were the Marfa & Marietta Mining Co., and the average price received was \$45.17 f. o. b. Marfa. The Heim & Dewees furnace was not started until early in 1902, and neither H. H. H. & Parker nor John Gaughran made any production during 1901. Both produced in 1899 and 1900.

## QUICKSILVER PRODUCTION OF THE WORLD. (a) (IN METRIC TONS.)

from official reports of the respective governments and direct reports of the producers to THE MINERAL INDUSTRY. The figures for Austria and Italy for 1899 are due to V. Spirek, that for Russia to the sole producer, for Spain to the *Revista Minera*. (b) Estimated imports. (c) Estimated.

*tria.*—Samples of cinnabar ore from the Spizza and Nehaj mines in Austria yielded by assay as follows: Samples Nos. 1, 2 and 3 from Spizza, 6, 4.56%, and 1.49% Hg, respectively. Sample No. 4 from Nehaj yielded 6% Hg and 94.4% BaSO<sub>4</sub>. The total production of quicksilver in Austria in 1901 amounted to 512 metric tons, while Hungary produced about 40 metric tons.

*na.*—The quicksilver mines in Kwei Chou Province were worked by an

English company during the latter part of 1901, which produced up to Jun 1902, about 500 flasks of quicksilver, which was sold in Hong Kong. A large amount of machinery is being transported to the mines, and more extensive work is expected in the near future.

WORLD'S PRODUCTION OF QUICKSILVER  
IN METRIC TONS

## CERMAK-SPIREK SHAFT FURNACE FOR QUICKSILVER ORES.

ak-Spirek furnace (see illustrations, pp. 560 and 561) was built in ble-shaft furnace for a daily capacity of from 12 to 15 tons of ore. st upon 6 columns (covered with sheet iron to prevent seepage of nd measure 1·2 m.×1·2 m.×5·1 m. in height. The contents of the ported on movable round plates which when moved aside permit the spent ore. The ore, broken to sizes ranging from 35 mm. to harged with 2% charcoal in quantities of 500 kg. every two hours. l quicksilver and the combustion gases are conducted through two ak-Spirek condensers.

importance is the Cermak charging apparatus, which is intended to scape of gas during charging. The charger is operated by a lever r protected from the noxious gases. It consists of a spitzkasten ing, the charging funnel with water-sealed cover and the carriage At the moment of charging, a passage is made between the d charging funnel by opening the cover, bringing forward the opening of the spitzkasten, these operations being performed by the lever as shown in the drawings. The draft is produced by ntillator One operator is necessary, who can attend to the charg- oval, and the costs with this furnace are so small that 0·01% eated profitably. The furnace, with condensers, costs 8,000 fr., Amiata these furnaces are employed exclusively. In regard to the d further treatment of the stuppe, see THE MINERAL INDUSTRY, 178 and Vol. VIII., p. 490.

FIG. 1. DETAILS OF CHARGING DEVICE.

## RARE ELEMENTS.

BY VICTOR LENHER.

AN element hitherto unknown except in combination has been prepared by Moissan by applying the electric furnace to the reduction of niobite. The new elementary metal is niobium and in many respects it resembles boron and silicon. Several rare earths whose elementary character has been repeatedly doubted have recently given undoubted proofs of complexity. According to Baskerville, thoria, one of the main constituents of the incandescent gas mantle, appears to break under certain fractionations into old thoria and a new body which is provisionally called "Carolinium."

The radioactive substances which possess the peculiar property of emitting light have been studied with the view of ascertaining the cause of their strange behavior. Thus far but little knowledge has been obtained of the reasons why they exhibit their characteristic properties, except that it be an inherent property of certain new elements whose properties are very little known at present. These elements—if they can be called such—seemed to be found in nature with other rare elements, as uranium and thorium, which also show unusual properties. The fluorescence of certain uranium compounds and the behavior of thoria in the incandescent mantle are so well known that they need no further comment, yet it is with these two elements that substances possessing radioactivity are found.

The use of liquid air as a cooling agent has enabled Pictet to obtain liquid oxygen from the atmosphere, thus rendering cheap oxygen a possibility. He shows 90% oxygen can be produced at 0.013 fr. per cu. m., or less than the selling price of ordinary illuminating gas. The production of oxygen at such a figure means a complete revolution in industrial processes; it would mean the use of the oxyhydrogen blowpipe as a commercial agent both for the economical production of a high temperature and for the cheap production of light with an incandescent lime or zircona medium. These results, coming as they do from Pictet, are of great weight.

As a result of the inquiries and investigation of the International Commission on Atomic Weights, it seems likely that  $O=16$  will be universally accepted as the standard, at least for some time. Much expression has been given as to whether the standard should be  $O=16$  and  $H=1.08$  or  $H=1$  and  $O=15.88$ . In all prob-

by the two standard tables of atomic weights based on the respective values of  $O=16$  and  $H=1$  will be continued in use.

**Argon, Neon and Helium.**—In the evaporation of a large amount of liquid air residue is obtained which consists of krypton, xenon, and argon. Argon is the most volatile and the gases are separated by Ramsay and Travers<sup>1</sup> by alternate distillation and liquefaction. To obtain neon and helium the escaping gas from the air liquefier is used. The gas which is mainly nitrogen is liquefied and air is run through it, the first portion to evaporate contains most of the neon and argon together with oxygen, nitrogen and argon. The oxygen and nitrogen are separated in the usual way and the neon and helium fractionally separated from argon. Neon is obtained free from helium by several fractionations at the temperature of boiling hydrogen. The densities given are argon=19.96, krypton=40.88, xenon=64. Argon boils at  $-186^{\circ}\text{C}$ ., krypton at  $-151.7^{\circ}\text{C}$ ., neon at  $-109^{\circ}\text{C}$ . The spectra have been studied by Baly; that of neon is orange pink, krypton is pale violet and xenon is sky blue. These gases find no place in our present periodic table of the elements, but appear to form a series by themselves.

In studying the occurrence of nitrogen and helium in uranium and thorium minerals, Kohlschütter observed certain experimental data showing that helium is combined in these minerals. When samarskite is heated in carbon dioxide, helium is completely driven off. It has been impossible, however, to synthesize a helium compound. Dewar in his work at low temperatures, considers helium to have a critical temperature below  $9^{\circ}$  absolute scale and even when it finally solidifies, its evaporation will not give the absolute zero. To get  $1^{\circ}$  lower in temperature another gas would have to be found as much more volatile than helium as the latter is than hydrogen.

**Barium.**—By the electrolysis of a solution of barium chloride using a mercury cathode, Guntz<sup>2</sup> prepares barium amalgam which, when heated to  $1,000^{\circ}$ , gives metallic barium free from mercury. The metal is white as silver, soft as lead and melts at dull redness, while at bright redness it readily volatilizes. It oxidizes rapidly in the air, giving the white oxide, and like lithium and calcium reacts with liquid ammonia an ammonium compound which, however, is not stable. Metallic barium easily decomposes water and alcohol.

**Boron.**—A number of new metallic borides have been obtained by Tucker and Gledhill,<sup>3</sup> who fused in the electric furnace an intimate mixture of boron with various elements. Borides of tungsten, chromium, zirconium and molybdenum have been obtained, all being hard crystalline bodies of high specific gravity, high melting point and attacked by acids with difficulty. Orlow has examined a specimen of commercial boron from Merck and found small transparent grains of boron trioxide, a little iron and about 9% of water. The latter was only expelled at  $1,100^{\circ}\text{C}$ . In 1895 Moisson observed that amorphous boron prepared by the commercial way, contained only 50% B, the remainder being hydride, oxide, boric acid and the sodium and iron borides. The element is conveniently obtained in the amorphous condition by heating borax with magnesium powder,

<sup>1</sup> *Proceedings of Royal Society*, 67, 323, 1901.

<sup>2</sup> *Comptes Rendus*, 133, 872, Nov. 25, 1901.

<sup>3</sup> *Proceedings of Chemical Society*, 17, 1901, p. 238.

while the crystalline variety is obtained by dissolving this amorphous powder in a fused metal as aluminum, and obtaining it as crystals on cooling. Perboric acid is prepared by the electrolysis of an orthoborate. A solution appears at the anode which bleaches potassium permanganate and liberates iodine from potassium iodide.

*Cæsium*.—The mineral pollux, one of the chief sources of this metal, is decomposed by Chabrie with 100 times its weight of pure hydrofluoric acid. He prepares the acid sulphite by saturating the alcoholic solution of the carbonate with sulphur dioxide. The sulphite appears as white crystals, the thiosulphate as colorless needles and the dithionate as hexagonal plates. The bromide, iodide, acid fluoride, chromate and bichromate also appear as well-defined salts.

As a continuation of his work on cæsium, Wells<sup>4</sup> purifies cæsium salts by precipitation of the double chloride with lead tetrachloride. He uses less concentrated hydrochloric acid than Godeffroy. One-half to one-third of the total volume of hydrochloric acid answers very well as the solution can then be filtered through paper. To such a solution, antimony trichloride is added until no more precipitate forms. The precipitate is collected on a filter and washed with hydrochloric acid. To the filtrate from the antimony salt without concentrating, lead nitrate is added at the rate of from 2 to 3 g. per liter. Chlorine is passed in to saturation and, after standing a few hours, the liquid is decanted from the precipitate of  $\text{Cs}_2\text{PbCl}_6$ , which is usually colored dark green from antimony salts. The precipitate is boiled with dilute ammonia and the ammonium salt decomposed by boiling with nitric acid when the nitrate is formed which may be fused. The nitrate may be readily recrystallized. The carbonate is obtained by treating the nitrate with oxalic acid and fusing in a platinum crucible. The purest cæsium compounds are best obtained by crystallizing  $\text{CsCl}_2\text{I}$ . This compound is prepared by treating the nitrate with 10 parts hydrochloric acid (1 to 10) and the requisite amount of iodine, and dissolving just below boiling, from which latter the yellow salt crystallizes on cooling. One or two recrystallizations give a very pure product. This trihalide gives pure cæsium chloride by heating just below fusion. When cæsium nitrate is evaporated with strong nitric acid the last of the acid is expelled with difficulty, due to the formation of an acid nitrate. Cæsium forms two acid nitrates with one and two molecules of nitric acid respectively. It also forms a double nitrate with ferric nitrate and one with bismuth nitrate. Five double fluorides of cæsium and antimony, containing different proportions of the two simple salts, appear. These are of white color, soluble in water and are formed by dissolving cæsium carbonate and antimonious oxide in hydrofluoric acid and crystallizing the solution. Cæsium periodate, prepared by the action of periodic acid on cæsium carbonate, appears in white plates which are but sparingly soluble in cold water.

*Cerium*.—Sterba<sup>5</sup> prepares pure ceria by subjecting cerous nitrate, made from monazite by the method of Debray, to the oxidizing action of the electric current, which yields a perfectly pure cerium compound. The ceric oxide was colored from yellow to rose, due to the presence of nitride. When nitride is absent the oxide is pure white. Ceric oxide, heated in hydrogen, is incompletely reduced,

<sup>4</sup> *American Chemical Journal*, 26, 265, September, 1901.

<sup>5</sup> *Comptes Rendus*, 133, 231, July 22, 1901.

$\text{O}_2$  being formed. Zinc also reduces it. When fused with common salt, wax, or potassium sulphate, it appears in colorless, transparent cubes or combinations of cubes and octahedrons.

According to Bloxam,<sup>6</sup> the mass and weight of an incandescent mantle may be reduced from 0.60 g. to 0.35 g. and the ceria very much increased. These very desirable results are obtained by the addition of a substance which has a tendency to sinter, such as silica or an organic compound. The example given is: 45 g. thorium nitrate, 0.95 g. cerium nitrate, 20 g. ammonium nitrate, dissolved in 14 g. water and 11.2 g. of a dialyzed solution containing 2%  $\text{SiO}_2$ . A fabric made of No. 100 cotton containing 120 meshes in every turn of the knitting and 16 turns per cm. is impregnated with this solution and burned as usual.

Bleichrode<sup>7</sup> has patented a mixture for automatically lighting gas by soaking vegetable tissue in a concentrated solution containing 1 part thorium nitrate, 1 part platinum chloride and 0.1 part of cerium nitrate. The tissue is burned in the gas, the ash molded into pellets and heated to redness.

**Fluorine.**—The monograph of Moissan on fluorine has recently appeared and shows that the isolation of fluorine was the result of years of patient painstaking work. Full details of the physical and chemical properties of the element have been worked out. When fluorine is free from hydrofluoric acid, the gas has so little action on glass that many chemical reactions can be readily observed. Moissan and Lebeau<sup>8</sup> have obtained the new gas, sulphuryl fluoride, by passing fluorine into sulphur dioxide in an apparatus so arranged that the two in coming into contact may immediately be combined by means of highly heated platinum. Unless such an arrangement is made, the union of the gases is delayed and then subsequently takes place with explosive violence. Sulphuryl fluoride boils at  $-10^\circ$ , melts at  $120^\circ$ , is colorless, odorless and not very active. The determination of fluorine in a fluoride, decomposable by acid, as fluorspar, is effected by Mark<sup>9</sup> by treating 3 g. dry silica and 0.2 g. fluorspar with 40 c.c. concentrated sulphuric acid. The mixture is heated to from  $120$  to  $135^\circ$ , and the silicon fluoride conducted into potassium fluoride solution; potassium silicofluoride is completely insoluble in alcohol and is precipitated by adding an equal volume of alcohol. The precipitate is dried at  $100^\circ$ .

**Gallium.**—In their examination of atmospheric dust and soot from various sources, Hartley and Ramage call attention to the wide distribution of this element in aluminous minerals, in flue-dust from various sources, in atmospheric dust, and in many iron ores.

**Hydrogen.**—The physical properties of liquid hydrogen have been more carefully studied by Dewar, who finds by means of a helium thermometer that its boiling point is  $20.5^\circ$  on the absolute scale. The solid melts at  $16^\circ$ . Thus the lowest temperature recorded is  $14.5^\circ$ . The latent heat of liquid hydrogen at its boiling point is 200 units, while that of the solid is 16 units. The specific heat of hydrogen between its melting point and its boiling point is 6, which is the highest of any known substance, and shows that it obeys the law

<sup>6</sup> English Patent No. 15,030.

<sup>8</sup> *Comptes Rendus*, 132, 374, Feb. 18, 1901.

<sup>9</sup> *Journal of the American Chemical Society*, 23, 825, November, 1901.

of Dulong and Petit. Its surface tension at the boiling point is one-fifth that of water.

Hydrogen peroxides higher than the ordinary dioxide have recently been claimed. The hydrogen from palladium hydride gives oxidation products which oxidize indigo more rapidly than the ordinary dioxide. The treatment of persulphuric acid with potassium permanganate and the action of hydrogen dioxide on potassium permanganate in the cold gives products which are very energetic oxidants. It is very doubtful whether these are true higher peroxides.

*Indium.*—This element is characterized by an indigo blue line in the spectrum. It is best detected microchemically according to Kley as the double chloride with rubidium by adding a small fragment of rubidium chloride to a solution of indium hydrate in hydrochloric acid. Colorless rhombic octahedral crystals separate. The reaction is delicate to 0.00024 mg. indium. Cæsium chloride gives a more delicate reaction but the crystals are very small and indistinct. Ammonium salts should not be present in carrying out the test as ammonium indium chloride is soluble in hydrochloric acid. Indium may be separated from other metals as hydroxide. From the trivalent metals, the separation by ammonia is followed by treatment with ammonium carbonate in which indium dissolves and from which it can be precipitated by oxalic acid. When little indium is present, it is better to use the rubidium chloride separation. Renz quantitatively precipitates indium hydroxide by the addition of dimethylamine to the hot solution. This hydrate, like alumina and gold hydrate, is feebly acid and gives salts with metals like magnesium. Indium molybdate is a white voluminous precipitate obtained by the addition of ammonium molybdate to indium solutions; it can be used to separate indium from zinc. Indium forms alums with rubidium and cæsium and by boiling indium-cæsium alum in dilute solution, indium oxide is precipitated in pure condition. The physical constants of indium show it to have a valence of four and to resemble iron and aluminum, although it resembles the zinc group in that it forms an amalgam.

*Iridium.*—The separation of the platinum metals, as described in THE MINERAL INDUSTRY, Vol. IX., p. 572, has been much simplified by Leidie, especially for use in the commercial extraction of platinum and iridium. The ore is treated with hot aqua regia, evaporated to dryness, heated to 105 or 110°C. and dissolved in water. The solution is treated with sodium nitrite at 70°C. until neutral, sodium carbonate is added and chlorine passed through after filtering. The ruthenium and osmium pass off as volatile oxides. Instead of treating the solution with ammonium chloride which precipitates the platinum and palladium, the hydrochloric acid solution is made alkaline with soda and the two metals are precipitated by formaldehyde and may be separated in the usual way. The substitution of potassium chloride and the use of formaldehyde avoid the objectionable palladao- and platino-amines which are produced by ammonia, as well as the ignition necessary to drive away ammonium chloride, an operation which is attended with a great deal of trouble when operating on a large scale. The iridium and rhodium are separated either by potassium or ammonium chloride and chlorine, the iridium being precipitated.

*Neodymium.*—Matignon<sup>10</sup> has found that neodymium chloride deposits as

$\text{NdCl}_3 \cdot 6\text{H}_2\text{O}$  in rose-colored deliquescent crystals from hydrochloric acid solution at the ordinary temperature. The salt is very soluble in water. The concentrated solution dissolves neodymium oxalate and the insoluble oxalates of the other rare earths, and on cooling crystals of the chloro-oxalates separate. The hydrated salt is decomposed on drying. The anhydrous salt is prepared by transforming the sulphate into sulphide in hydrogen sulphide gas, then transforming the sulphide to chloride by means of hydrochloric acid gas. The anhydrous chloride is rose colored and fuses easily to a rose-colored deliquescent mass. This compound dissolves in water with a hissing noise. The metal may be obtained by treating the anhydrous chloride with sodium.

*Niobium.*—Moissan<sup>11</sup> has prepared metallic niobium from powdered columbite mixed with sugar carbon by heating the mixture 7 or 8 minutes in the electric furnace with a current of 1,000 amperes at 50 volts. All of the manganese and most of the iron and silicon were volatilized leaving a gray crystalline mass of niobium and tantalum containing 2.18 to 2.34% C. This alloy was dissolved in nitric and hydrofluoric acids and niobium oxide separated by the Marignac method. Eighty-two parts niobic acid were mixed with 18 parts sugar carbon, the mass mixed with turpentine and heated 3 to 4 minutes with a current of 600 amperes at 60 volts. The fused metal which was obtained is so hard it scratches quartz. It cannot be fused in the oxyhydrogen blowpipe but readily fuses in the electric furnace. It burns in fluorine at 205°C.; chlorine gives the yellow chloride. Bromine attacks it at a higher temperature, while iodine without action at the red heat. At 400°C. the metal burns in oxygen and at higher temperature in air. Alloys of niobium are obtained with difficulty; sodium, potassium, and magnesium can be distilled over the fused metal without combining with it while only a small percentage of niobium combines with iron. While the metal does not decompose water, even at 600°C., at this temperature burns in sulphur dioxide and nitric oxide. At a red heat phosphoric anhydride is reduced to phosphorus and carbon dioxide to carbon. Hydrofluoric acid attacks the metal but hydrochloric and nitric acids as well as aqua regia are without action. Boiling sulphuric acid is colored brown and at the same time niobic acid is precipitated. A mixture of nitric and hydrofluoric acids rapidly dissolves niobium.

Alloys of niobium and tantalum have been prepared by Smith and Hamilton,<sup>12</sup> by reducing columbite with carbon in the electric furnace and adding the resulting matte with metallic copper, which forms a product resembling metallic copper. An analysis showed: copper, 95.01%; niobium and tantalum oxides, 2.01%; gangue, 2.57%. The matte resulting from the reduction of 100 parts columbite and 15 parts carbon was fused with an excess of metallic iron. The powder was brittle and steel gray in color and contained: Fe, 59.76%; Ta, 18.77%; Fe, 15.73%; W, 5.12%; gangue, 5.76%. A matte of niobium and tantalum, a matte of titanium from rutile, and an excess of metallic iron fused in the electric furnace yielded an extremely hard gray colored alloy which contained: Fe, 80.02%; Nb, 10.15%; Ta, 2.91%; Ti, 3.18%;

<sup>11</sup> *Comptes Rendus*, 133, 21, July 1, 1901.

<sup>12</sup> *Journal of the American Society*, 23, 151, March, 1901.

C, 1.99%; Si, 2.14%. A current of from 145 to 165 amperes at 35 volts was used in this work.

Levy<sup>13</sup> analyzes samarskite by fusing one gram of the mineral with six grams potassium acid sulphate. The cold mass is extracted with warm water leaving the silicon, niobium and tantalum as oxides. The filtrate is heated with hydrochloric acid and precipitated by ammonia and the filtrate boiled to reprecipitate any uranium oxide or alumina. The filtrate from this is examined for calcium and magnesium in the usual manner. The ammonia precipitate is dissolved in hydrochloric acid, the alumina separated by sodium hydrate, the rare earths separated as oxalates and converted into oxides. The iron and uranium are separated by means of ammonium sulphide and carbonate. The uranium is weighed as  $U_3O_8$  and  $UO_2$ . The silicon, niobium and tantalum oxides are again fused with potassium bisulphate, the filtrate is treated as above and the residue treated with hydrofluoric acid, which removes the silica. The niobium and tantalum are separated by means of potassium fluoride and hydrofluoric acid. The silica is checked in the original mineral by determining it with hydrofluoric and sulphuric acids. The rare earths are separated by dissolving the ignited oxalates in hydrochloric acid with the aid of a little potassium iodide, the solution evaporated to dryness, the residue dissolved in a small quantity of water, treated with saturated potassium sulphate and allowed to stand for two days. The yttria solution is precipitated by ammonia, ignited and weighed. The cerium group precipitate of double sulphates is dissolved in hydrochloric acid, precipitated by ammonia, ignited, and weighed. A sample of samarskite thus analyzed gave:  $SiO_2$ , 2.86%;  $Nb_2O_5$ , 31.52%;  $Ta_2O_5$ , 16.63%;  $Fe_2O_3$ , 10.68%;  $Al_2O_3$ , 3.07%;  $U_2O_3$ , 12.13%;  $CaO$ , 3.34%;  $MgO$ , 0.1%;  $CeO_2$ , 1.65%;  $Yt_2O_3$ , 14.32%; insol. oxides, 0.79%; ignition loss, 2.48%. Total, 99.57%.

**Nitrides.**—Beilby and Henderson<sup>14</sup> have submitted various metals to the action of ammonia at high temperatures. Iron in the compact state, heated in a current of ammonia, is more or less completely converted into the nitride  $Fe_3N_2$ , the essential conditions being the presence of a large excess of ammonia and a temperature of from 450 to 850°C. The nitride is a silver-white body readily soluble in dilute hydrochloric or sulphuric acids. Heated to redness in hydrogen it is completely decomposed into iron and hydrogen. Pure iron is rendered hard and brittle as steel by absorption of small quantities of nitrogen. Tubes of malleable iron exposed seven days to ammonia at 700°C. becomes brittle as porcelain, while charcoal iron becomes so hard that it can be used as a drill. In a similar manner,  $Co_4N_2$  is produced at 470 to 500°C. yielding a dull gray powder which in its properties resembles iron nitride.  $Ni_3N$  is formed at 400 to 600°C. It is black and resembles cobalt and iron nitrides. Copper is very sensitive to the action of ammonia at high temperatures, the nitride is easily decomposed by heating in hydrogen and can only exist within a very narrow range of temperature.

**Osmium.**—The use of osmium filaments in incandescent lamps has caused quite an active demand for this metal. Its price has been quoted during the year at \$21 per oz., a slightly higher figure than gold. Welsbach has been able to

<sup>13</sup> *Analyst*, 26, 64, 1901.

<sup>14</sup> *Journal of the Chemical Society*, 70, 1245, November, 1901.

use osmium to a filament and substitute it for carbon in incandescent electric lights. It withstands a higher temperature, is more durable and gives a higher illuminating power. The osmium lamps can be operated at 25 and 50 volts and with an efficiency of 1 Watt per candle power. It gives a light of from 2 to 10 candle power. Osmium is one of the older metals of the platinum group, was discovered in 1803, and is found in nature associated with iridium and other of the platinum metals. The metal usually appears as a dark gray powder. One of the compounds which has been of commercial importance is the oxide which comes into trade as osmic acid. It is used as a black stain in optical apparatus.

**Palladium.**—S. Cowper-Coles<sup>144</sup> describes a process of making non-tarnishable cathodic reflectors by the use of a silvered glass mold on which copper is electrolytically deposited, the metal and mold being subsequently separated by immersion in lukewarm water, the different co-efficients of expansion serving to separate them easily. Palladium is then deposited uniformly from an electrolyte of the soluble chloride of palladium and ammonium dissolved in a concentrated solution of neutral sodium citrate. By rapid rotation of the metal mold the deposit of palladium is very uniform, the thickness of the deposit being from 70 to 80 grains of palladium per sq. ft. of surface. Palladium is practically non-corrodable, and resists to a remarkable degree the heat of the arc light.

The hardness of palladium compared with other metals, as represented by the number of centigrams weight on a diamond point required to produce a scratch, is as follows: Electrolytic nickel 10, Sheffield plate 10, electrolytic antimony 9, electrolytic platinum 9, electrolytic palladium 8, electrolytic chromium or copper 7, electrolytic cadmium 4.5, electrolytic silver (burnished) 4, silver deposited chemically 2.

**Radium.**—The examination of the spectrum of radium and polonium shows a number of new lines which seem to belong to these bodies. Curie and Debierne show that while radioactivity is not produced by direct rays from a radium salt, it is communicated by the air from molecule to molecule from the radium salt to the body which is excited. It is possible to communicate radioactivity to distilled water by distillation of a radium chloride solution which has been allowed to stand several days, or by placing a radium salt solution and distilled water in separate dishes in a perfectly closed space. The same result is obtained by placing a celluloid capsule containing a radium salt in distilled water. The energy may be transmitted by radiation and by a kind of conduction passing through gases and liquids but not ordinarily through solids. Becquerel shows that secondary radioactivity consists of a portion not deviated by a magnetic field and easily absorbed; a portion which is deviated by a magnet and identical with cathode rays; and a portion not deviated by a magnetic field and very penetrating. It is worthy of note that radium rays cause skin wounds very similar to X-rays.

Hofmann has carefully studied radioactive lead from the mineral bröggerite which is a uranium, thorium and lead uranate. An analysis of this mineral from Raade near Moss in Norway, shows  $\text{UO}_2$ , 50%;  $\text{UO}_3$ , 27.83%;  $\text{ThO}_2$ ,

<sup>144</sup> *Electrochemist and Metallurgist*, April, 1901.

4.96%; yttria earths, 4.56%;  $\text{Fe}_2\text{O}_3$ , 0.46%;  $\text{Bi}_2\text{O}_3$ , 0.35%;  $\text{PbO}$ , 9.06%. The radioactivity of lead sulphate from bröggerite and other minerals may be increased by boiling it with a sodium carbonate solution converting the carbonate into chloride and crystallizing from water. The most soluble fractions are the most active. The active sulphate shows a blue fluorescence when exposed to cathode rays, and its spark spectrum shows a characteristic violet line. In many respects radioactive lead is chemically similar to ordinary lead. It may be precipitated as hydroxide, sulphide, sulphate, chloride, or iodide. The chloride is more soluble than lead chloride, while two sulphates appear which show the metal to have a valence of two and four. The atomic weight of radioactive lead is probably about 260.

*Samarium*.—In 1885 Crookes in his work on electric phosphorescence in vacuum observed a band in samaria which he called the "anomalous line" as it disappeared in presence of lime. Demarcay now gives the spectrum of a new oxide which shows no indications of the spectra of samarium, and only traces of gadolinium. The anomalous line of Crookes is the strongest line in this spectrum. The new lines are considered to belong to a new element which has been named europium. As an element samarium is not at all sharply defined and it would not be at all surprising to have its character much more simplified. Samarium carbide has been prepared by Moissan in the electric furnace and like a number of the carbides of the more poorly defined elements, on treatment with water yields a mixture of solid, liquid and gaseous hydrocarbons, the hydrocarbons being of the acetylene, ethylene, and methane series.

*Selenium*.—This element which forms a gaseous hydride has proved itself to be an interfering agent in carrying out the Marsh test for arsenic. The source of the arsenic in beer which caused the recent poisoning epidemic in England has been attributed to the impure sulphuric acid used in the manufacture of the brewing sugar. Berry<sup>15</sup> has observed selenium in various acids and other materials and finds that like arsenic, it has the curious property of distributing itself over many manufactures into which it may be brought into contact. It is demonstrated that cotton wool moistened with lead acetate will remove selenium in the Marsh test and the arsenic may be subsequently deposited uncontaminated. Perreau has shown that Röntgen rays act similarly to light on selenium, and Bloch has observed that the emanations from radioactive barium carbonate act on selen cells similarly to feebly diffused light, lowering the resistance materially. By the electrolysis of potassium selenate containing a little free selenic acid. Dennis and Brown<sup>16</sup> obtained a white solid which contained as high as 74.44% perselenate. The substance is a powerful oxidant, oxidizing manganese dioxide to permanganate and losing oxygen when the solution is warmed.

*Silicon*.—Ferrosilicon is now being produced on commercial scale at Meran in the Austrian Tyrol and in France by treatment of scrap iron, quartz and coke in the electric furnace. Five thousand one hundred and twenty K.W. hours are required for the production of a ton of 78% ferrosilicon. The selling price of the material is based on the silicon content; 21% sells at about \$40 per ton.

<sup>15</sup> *Journal of the Society of Chemical Industry*, 20, 322, April 30, 1901.

<sup>16</sup> *Journal American Chemical Society*, 23, 358, May, 1901.

Silicon improves the physical properties of steel where little carbon is present and it is of value in casting steel. Iron silicide as well as those of a number of the metals have received considerable attention at the hands of Moissan and Lebeau and the latter has shown that commercial ferrosilicon may contain the three silicides  $\text{SiFe}_2$ ,  $\text{SiFe}$ , and  $\text{Si}_2\text{Fe}$ . The silicon copper manufactured by the Cowles Electric Smelting & Aluminium Co., at Lockport, N. Y., is marketed at 34c. per lb. in 500 lb. lots. Silicon copper is successfully used as a deoxidizing agent in casting bronze, brass, and copper. It is broken into small pieces and added to the alloy or metal after the other ingredients are in the crucible.

Cobalt silicide,  $\text{CoSi}$ , similar to  $\text{FeSi}$ , is prepared by Lebeau in the electric furnace by heating 400 g. copper silicide with 40 g. cobalt for 4 to 5 minutes with a current of 950 amperes at 50 volts. It appears in prismatic crystals which are so hard that they easily scratch glass. It has a specific gravity of 6.3 and is difficult to attack by the ordinary reagents.

*Tellurium.*—Mathey<sup>17</sup> states that the presence of minute quantities of tellurium in bismuth renders the metal unsalable and it is necessary to remove every portion of the tellurium in refining crude bismuth. He worked up the alkaline residues obtained, and by means of hydrochloric acid and sodium sulphite obtained a specimen of crude metal weighing 25 kg.

The alloys of tellurium with lead and antimony have been studied by Fay and Gillson.<sup>18</sup> In all the alloys prepared, lead telluride is a common constituent. Its amount gradually increases as tellurium is added to lead until the whole mass is lead telluride, and then gradually decreases until the whole mass is pure tellurium. Tellurium forms a definite alloy with lead telluride but the latter does not form such a compound with lead. The antimony-tellurium alloys are in many respects similar to the lead alloys, the alloys being formed with tellurium and antimony telluride.

Carnot divides the Kalgoorlie telluride ores into sylvanite, a bitelluride of gold and silver having a crystalline texture, calaverite, a bitelluride analogous to sylvanite but less crystalline and containing less silver, and coolgardite, or sesquitelluride of gold, silver and mercury, in which these metals are in variable quantities.

The tellurides of Coolgardie, West Australia, occur in a schistose amphibolite, the upper parts of which carry free gold. The minerals are sylvanite, calaverite, petzite, and copper ore much like enargite in composition. In a number of the rich sulphide ores from the Hauraki gold fields in New Zealand, tellurium has been found, but it is always in the ores along with copper. Not sufficient has been found to indicate how it is combined.

I have questioned the chemical composition of the telluride ores<sup>19</sup> and have shown that all of the natural tellurides of gold precipitate metallic gold from solution when brought in contact with them. As a chemical compound cannot precipitate one of its constituents it is a question whether the tellurium and gold are chemically united in these minerals. In the mines in which the tel-

<sup>17</sup> Paper read before the Royal Society, March 14, 1901.

<sup>18</sup> Paper read before the American Institute of Mining Engineers, November, 1901.

<sup>19</sup> Paper presented before the American Chemical Society, December, 1901.

luride ores are worked, specimens of native gold are frequently found in the upper parts of the mine. The native gold is a pseudomorph after the tellurides and has doubtless been deposited by a gold-bearing solution coming in contact with the tellurides. Another striking point is that metallic tellurium quantitatively precipitates gold from solution and specimens of native tellurium frequently carry a small per cent. of gold.

The quantitative precipitation of tellurium is effected by Gutbier by means of hydrazine in neutral solution. The method is applicable to both tellurites and tellurates.

A series of determinations of the atomic weight of tellurium have appeared but all show that its atomic weight is higher than that of iodine and that tellurium still remains an exception to the periodic law.

Mylius<sup>20</sup> has shown that ordinary telluric acid,  $\text{H}_2\text{TeO}_4 \cdot 2\text{H}_2\text{O}$ , when heated to  $140^\circ\text{C}$ . is converted into allotelluric acid  $(\text{H}_2\text{TeO}_4)_n$ . This variety has five times the conductivity of the ordinary acid and forms white precipitates with solutions of guanidine carbonate and albumen. In solution it slowly reverts to the ordinary acid. The physiological action of tellurium compounds have been carefully studied by Gies.<sup>21</sup> In many respects the action of tellurium in the body is like that of selenium, arsenic, and antimony. When tellurous oxide is inhaled it causes metallic taste, nausea, depression, and constipation, methyl telluride is excreted with the breath and skin, while methyl telluride itself when inhaled acts very similarly. Potassium tellurate has been used to reduce night sweats in consumptives, but on account of the obnoxious odor imparted to the breath the tellurates have not come into general use.

**Thallium.**—In the examination of atmospheric dust from various sources Hartly and Ramage have detected the presence of thallium. Pumice from Krakatoa contains this element, while lead chloride from Vesuvius also contains it. The detection of thallium is effected by Reichard by the use of a saturated solution of an alkaline picrate, a light yellow precipitate is formed. The test is delicate to about 0.5 per cent.

**Thorium.**—Baskerville,<sup>22</sup> in a paper on the complexity of thorium, announces a new element for which the name carolinium is proposed. Thorium hydrate was dissolved in hydrochloric acid and the solution exactly neutralized with ammonia. This solution was saturated with sulphur dioxide, yielding in a few minutes a basic sulphite, which was filtered off and ignited to oxide. The filtrate was precipitated by ammonia and ignited. The specific gravity of the oxide obtained in these fractions differ considerably. The sulphur dioxide precipitate had a density of 9.38, the soluble portion precipitated by ammonia had a density of 10.367 while the original oxide had a density of 10.1. By boiling the citrate solution, a precipitate is formed which when ignited has a specific gravity of 9.2 and a solution which when evaporated and ignited gives an oxide with a specific gravity of 10.5. The fraction of purest insoluble citrate shows the

<sup>20</sup> *Berichte*, 34, 2208, July 20, 1901.

<sup>21</sup> *American Journal of Physiology*, 5, 104, March, 1901.

<sup>22</sup> *Journal of the American Chemical Society*, 23, 761, October, 1901.

element to have an atomic weight of 223.2 while the other element contained if tetravalent would have an atomic weight between 260 and 280.

Metathorium oxide, according to Stevens,<sup>23</sup> is a variety of thorium oxide which has the same composition but different properties than the ordinary oxide. The hydroxide is less basic than the ordinary, it does not absorb carbon dioxide from the atmosphere and on standing in contact with water it is transformed into the ordinary hydrate. A recent analysis of monazite from New Granada shows 18% thoria, 25.02% ceria, 22.41%  $\text{La}_2\text{O}_3$ , 1.21%  $\text{MgO}$ , 2.13%  $\text{CaO}$ , 3.0%  $\text{SnO}_2$ , 28.23%  $\text{P}_2\text{O}_5$ , with traces of iron, zinc and sulphur.

According to Nernst there is no special catalytic action of the Welsbach mantle to which the high economy is due. As the material of the mantle radiates very little red light and few ultra red rays, it yields little energy in that part of the spectrum in which the maximum emission of heat usually takes place, the mantle is consequently enabled to absorb the full heat of the gas flame and thereby to radiate a relatively large volume of light.

*Titanium.*—The introduction of titanium into steel is said to increase its tensile strength. Steel containing 0.5% Ti is used for piano wire, needles and certain electrical purposes. Titanium steel thus far is largely confined to the experimental stage.

Brakes<sup>24</sup> modifies the Baskerville method for determining titanium by fusing 5 g. ore with an equivalent amount of sodium fluoride and potassium sulphate, in a platinum crucible, dissolving the fusion in 10% sulphuric acid and filtering into a 500-c.c. flask; 100 c.c. of this solution is placed in a Nessler tube and 5 c.c. of hydrogen peroxide added and mixed thoroughly. A comparison test is made by placing 100 c.c. of 10% sulphuric acid in a second Nessler tube and adding the number of cubic centimeters of a standard ferrous sulphate solution equivalent to the amount of iron present in 1 g. of the ore, 5 c.c. of hydrogen peroxide are added and standard  $\text{TiO}_2$  solution is added until the desired tint is obtained, the color being compared by reflected light. Great accuracy is claimed for the method.

*Uranium.*—Uranium ores are sold in Denver according to the percentage of uranium content: 10% ores are quoted at \$17.50 per unit, 10 to 15% ores at \$18 per unit, 15 to 20% ores at \$19 per unit, 20% and over at \$20 per unit. The ore finds a ready sale at these prices. A large quantity goes to France.

Kern<sup>25</sup> has made a detailed study of the technical estimation of uranium with the view of finding the most accurate and satisfactory method. Uranium can be separated from the copper group by means of  $\text{H}_2\text{S}$  in an  $\text{HCl}$  solution. From the third and fourth groups it is best separated by means of a saturated solution of sodium carbonate or by ether, followed by a saturated solution of ammonium carbonate. The separation from iron depends on the fact that ether extracts ferric chloride from an aqueous hydrochloric acid solution while uranyl chloride remains in solution. From the alkalies and alkaline earths, the best method of separation is the electrolysis of a dilute acetate solution in

<sup>23</sup> *Zeitschrift fuer Anorganische Chemie*, 27, 41, 1901.

<sup>24</sup> *Journal of the Society of Chemical Industry*, 20, 23, Jan. 31, 1901.

<sup>25</sup> *Journal of the American Chemical Society*, 23, 685, October, 1901.

presence of sodium acetate; hydrated protosquioxide of uranium appears on the cathode as a black deposit and this is ignited to  $U_3O_8$ , which may be weighed. The separation by means of ammonia in presence of ammonium chloride is best effected by boiling 20 minutes when the yellow slimy precipitate of ammonium uranate becomes darker and filters more readily. This precipitate is ignited to  $U_3O_8$ . The most rapid determination of uranium is accomplished by reducing a sulphate solution with zinc, magnesium, or aluminum, and titrating with potassium permanganate in an atmosphere of carbon dioxide. The results obtained this way are as accurate as by the gravimetric methods. Kollock and Smith separate uranium from barium, calcium, magnesium and zinc by the electrolysis of solutions of the acetate, nitrate, or sulphate, but cannot separate it from chromium and iron this way.

Uranium amalgam is prepared by Férée by the electrolysis of uranous chloride using a mercury cathode and separating the poles by a porous diaphragm. When the amalgam is heated to  $241^\circ\text{C}$ . in vacuum, the mercury is driven off, leaving a pyrophoric metal which burns brightly in air. Uranyl nitrate may be prepared on a large scale by the solution of the pentoxide, prepared by igniting ammonium uranate, in nitric acid of a specific gravity of 1.32.

Aloy has ascertained that for the preparation of metallic uranium in the electric furnace it is only necessary to use 15 to 25 amperes, while Moissan used 500 to 800 amperes at 45 to 55 volts. Uranium red, a complex potassium sulpho-uranate has been made by Kohlschütter<sup>26</sup> by treating potassium uranate solution with hydrogen sulphide, filtering rapidly, digesting the mass with potassium carbonate and extracting with alcohol, carbon bisulphide and ether to remove sulphur. When dry the substance is a carmine red powder. The ammonium and sodium compounds are also red and the barium compound is so stable toward carbon dioxide and hydrogen sulphide that it can be used as a pigment.

*Vanadium.*—There is very little demand for vanadium oxide in quantities by the steel manufacturers and the supply from the slags of the Creusot steel works in France, amounting annually to about 165,000 lb., is used as a mordant in dyeing. A large supply would admit of the use of vanadium in the manufacture of armor plate, projectiles and bronzes. H. Proctor Smith<sup>27</sup> has studied the extraction of vanadium from the standpoint of obtaining a ferrovanadium alloy to be used in steel-making. The ore treated is an impure lead vanadate from Spain, crushed to pass through a 0.125-in. mesh sieve and fused for 20 or 30 minutes with two parts sodium or potassium bisulphate. The fused mass is crushed and leached with water, the resultant solution is allowed to stand in contact with scrap iron, and the lead sulphate, silica and undecomposed ore separated. The iron is introduced for the purpose of insuring that the vanadium will be present as vanadic salt. The vanadium and iron hydrates are now precipitated gray or black in color by the addition of a 25% solution of caustic soda. The gelatinous precipitate is filter pressed, washed and dried, and contains about 18%  $V_2O_5$  to 77.5%  $Fe_2O_3$ . To make a ferrovanadium alloy the reduc-

<sup>26</sup> *Annalen*, 14, 311, 1901.

<sup>27</sup> *Journal of the Society of Chemical Industry*, 20, 1183, Dec. 31, 1901.

ion is effected in the electric furnace by carbon and aluminum or aluminum alone. A mixture of 8 parts dried oxides, 2 parts powdered charcoal and 1 part aluminum in small pieces subjecting to the action of the electric arc in a graphite crucible yields a brittle button of fine white granular fracture, which contains V, 16%; Fe, 70%; Si, 20% and Al, C, etc., 12%. A mixture of the oxides with granulated aluminum ignited by means of sodium peroxide and magnesium or aluminum gives a brittle yellow metallic button containing about V, 15%; Fe, 58%; Al, 26% and Si, 1.3%. When used in steel-making these alloys require the same care as ferrochromium or ferronickel, and they increase enormously the tensile strength and elastic limit of steel to which they have been added.

*Yttrium*.—By the fractionation of the crude oxides from gadolinite by means of their ethyl sulphates G. and E. Urbain<sup>28</sup> find that the gadolinium elements can be so completely separated that the yttria and ytterbia solutions do not show phosphorescent spectra. The atomic weight of ytterbium is given as 172.6 and that of yttrium as 88.6.

*Zirconium*.—In the extraction of lead from a specimen of euxenite from Brevig, for the examination of its radioactive properties, Hofmann and Prandtl<sup>29</sup> have found an earth in the sulphate residues whose properties indicate an unknown metal. The oxide is white, and cannot be reduced by hydrogen but when fused with potassium bisulphate becomes soluble. Alkalies give a white flocculent precipitate. From the analysis of the sulphate its atomic weight is about 17.8.

Boehm has patented<sup>30</sup> a glow body for use in the Nernst lamp, which is resistant to outer influences. Such a mixture consists of 90 parts zircona, 5 magnesia, 4 lime, 1 manganese sesquioxide. This mixture is made into a paste with a sugar solution and is squirted into threads or rods. In Nernst's early experiments magnesia was used as a glower. More recent experiments have shown zircona and the rare earths used in the Welsbach mantle are satisfactory. The Nernst lamp consists in using a refractory earth as an incandescent material, this substance being a nonconductor when cold but allowing the current to pass through after it is heated. The glower in the present lamp is heated by means of a thin porcelain tube wound with platinum wire. Automatic cut-outs throw out the heaters when the current is established through the glower. The lamp is thus automatically lighted now while in the earlier types outside heat was applied to heat the glower. The present design of lamps gives from 50 to 2,000 candle power and it is expected that the new lamp will meet a want, as the light given off closely approximates the quality of daylight and shows colors in their proper shades.

## SALT.

THE total production of salt in the United States, including that used for the manufacture of alkali and heavy chemicals amounted in 1901 to 20,566,661 bbl., as compared to 20,738,729 bbl. in 1900. The leading salt producing States rank in the order of maximum production and percentage of output as: Michigan, 7,729,641 bbl., 37.6%; New York, 7,286,320 bbl., 35.4%; Kansas, 2,087,791 bbl., 10.2%; and Ohio, 1,153,535 bbl., 5.6%. These four States furnished 88.8% of the total United States output in 1901.

(a) Amount inspected. (b) Includes the production of Pennsylvania. (c) Includes salt used for the manufacture of alkali. (d) Output in 1900 is estimated.

*Imports and Exports.*—The imports of salt during 1901 were 403,465,946 lb. (\$676,332), as against 415,775,592 lb. (\$633,192) in 1900; the exports of domestic salt amounted to 18,865,247 lb. (\$86,414) in 1901, against 15,021,861 lb. (\$65,410) in 1900, and the exports of foreign salt were 3,699,411 lb. (\$7,155) in 1901, as against 3,548,724 lb. (\$3,907) in 1900.

*California.*—The production of salt in 1901 was 601,659 bbl., against 455,271 bbl. in 1900, an increase of 145,388 bbl. during the year.

*Kansas.*—The mines of Rice County, near Lyons, are equipped with channelling machines and compressed air drills, and are working an 18 ft. bed of salt by the pillar and chamber method. The salt is crushed, graded and shipped without refining. Late in 1901 the Hutchinson-Kansas Salt Co. began the sinking of a deep well to prospect as far as the drilling machinery will permit. The wells now average from 750 to 800 ft. in depth.

*Louisiana.*—The success of the Myles Salt Co., of Weeks Island, Iberia Parish, in sinking through the quicksand by the caisson method, has contributed not a

little to the possibilities of salt production in Louisiana. Steel and wood caissons were used until the salt bed was penetrated, when walls of the shaft were fused with blow-pipes and covered with pitch and asphalt overlaid with cement. The output of salt in the State increased from 386,744 bbl. in 1900, to 451,430 bbl. in 1901.

*Michigan.*—During 1901 Michigan increased its salt production by 883,956 bbl., as compared with 1900, thereby taking first rank in the salt producing States. The Solvay Process Co. completed its additional installations at Detroit in the latter part of 1901, and the Pennsylvania Salt Co. purchased land on the Detroit river, near the Michigan Alkali Works, at Wyandotte, for the purpose of erecting an electrolytic plant for the manufacture of alkali and bleach by the Bell patents.

*New York.*—The production of salt during 1901 showed a decrease of 837,230 bbl., as compared with 1900. The report of the National Salt Co. for the year ending December 31, 1901 shows \$5,758,250 common, and \$3,758,250 of preferred stock beside the 12,417.5 shares each of common and preferred stock deposited with the American Trust Co., of Cleveland, O., pending litigation with the United Salt Co. The accounts show profits as follows: From the New York Department, \$290,581; from subsidiary companies, \$28,052; dividends, etc., \$156,465; total, \$475,098. Deductions are: Loss on Michigan Department, \$275,738; New York office, \$160,445; total, \$436,183, leaving a surplus of \$38,915 for the year, which added to the surplus from the previous year made a total of \$876,374. Total deductions were: \$155,314 for 1900 profit not received; bonds of subsidiary companies paid, \$40,000; dividends paid, \$651,172; total, \$846,486, leaving a balance at the close of the year amounting to \$29,888. An entirely new Board of Directors and Officers were elected during the latter part of the year. Early in 1902 articles of incorporation of the Oatka Mining Co. were filed at Albany. The capital stock is \$500,000, and the company proposes to compete with the National Salt Co.

*Utah.*—The output during 1901 was 334,484 bbl., compared with 267,857 bbl. in 1900. A discovery of a large body of rock salt was made near Gunnison, San Pete County, containing 98.88% NaCl, with impurities chiefly iron oxide. A plant manufacturing 2 tons per day has been started, and enlargements are contemplated during 1902.

#### THE WORLD'S PRODUCTION OF SALT.

*Bosnia and Herzegovina.*—The production of salt in Bosnia in 1900 amounted to 15,791 metric tons, while that of Herzegovina was 100,116 metric tons.

*Canada.*—The output in 1901 was 59,428 short tons, valued at \$262,328, against 62,055 short tons, valued at \$279,458 during 1900. Early in 1902 there were reports of the formation of a trust to consolidate the Canadian salt wells.

*China.*—The annual production of salt in the Tze-liu-ching district of China is estimated at 178,571 long tons. The district produces both oil and brine from wells which are sunk to a depth of from 2,200 to 3,300 ft. by means of churn drills, the operation taking in some instances as many as ten years to com-

plete. The gas is conveyed in bamboo pipes to the evaporating kettles made of cast iron, 4 ft. 9 in. in diameter and saucer-shaped, provided with extension sides

THE WORLD'S PRODUCTION OF SALT IN METRIC TONS.

made of iron plates luted with clay. This dish is set above a cup-shaped clay-lined hollow in the floor through the center of which the gas ascends.

*Japan.*—The output of salt in 1899 was 590,133 metric tons, which was produced chiefly from sea-water by solar evaporation only or by a combination of

stantaneous evaporation with artificial heating of the concentrated solutions. A small quantity of salt is produced from weak brine springs by artificial heating. About a hundred and forty thousand workmen are employed in the Japanese salt industry.

**Russia.**—The principal deposits of salt in Russia are in the following provinces: Tauria, Perm, Astrakan, Jekaterinoslaw, Charkow, Chersson, Orenburg, Caucasus, Ural, Turgai, and in the Transcaspian and Turkestan districts. The opening of the Perm-Kotlass Railway within the last few years has renewed the activity of the Urals which supplied all Russia, until discoveries of rock and brine salt in South Russia and the Volga region deprived Perm of its supremacy.

(a) From the official reports of the respective countries. For Austria, Hungary, Russia, Spain, and the United States, the production of all kinds of salt is given; Germany, rock salt and common salt; Greece, sea salt; France, rock and sea salt; Algeria, sea and rock salt; Italy, rock and salt from brine; United Kingdom, rock and brine salt; India, salt which is liable to British salt tax only, and does not include salt made in certain States. (b) Not reported in the official statistics. (c) Statistics not yet published. (d) The high value of salt in Austria and Hungary is due to the government monopoly of production and high taxation. (e) Rock and brine salt only. About 400,000 tons of sea salt is made annually. (f) No value given.

## SILICA.

UNDER this caption are grouped the various forms of silica that have a commercial or industrial value, including diatomaceous earth, tripoli, sand, silica brick, flint, pumice, sandstone and novaculite used in the manufacture of grindstones and whetstones. Sandstone for building purposes will be found under the heading "Stone," elsewhere in this volume.

*Diatomaceous Earth and Tripoli.*—Diatomaceous or infusorial earths were mined in the following localities during 1901: The Blue Hill, in Maine; on Troy Mountain, Troy, N. H., from which place the material is shipped to Keene to be calcined, bolted, and made up into cleaning and polishing powders; Framingham, Mass., where the product is burned and washed before it is marketed. In Calvert County, Md., infusorial earth was mined during the year. Hollow furnace brick and plastic asbestos cement is to be made from the infusorial earth recently uncovered near Wilmot, Va., and shipments were continued from the deposits of Esmeralda County, Nev. Deposits of infusorial earth of from 18 to 45 ft. in depth occur at Niederohe and Oberohe, northern Germany, from which large amounts are exported annually. The tripoli deposits of Murray County, Ga., were worked to some extent, and a limited quantity of the finely ground product was shipped. An unusual deposit of tripoli is that near Carthage, Mo., where it is found in a very compact but porous condition, so that it may be cut into shapes and used directly for water filters. The American Tripoli Co., of Seneca, Mo., made an unusually large production during the year, largely accounting for the increased value of the production for 1901 of both infusorial earth and tripoli, which amounted to a total of 4,020 short tons, valued at \$52,950 as compared with 3,615 short tons, valued at \$24,207 for 1900.

Extensive deposits of kieselguhr occur at Wyrallah, Lismore district, and Barraba and Cooma, New South Wales, and experimental shipments to Sydney have been made; the demand, however, is limited and mining operations have made but little progress. A deposit of infusorial earth varying in thickness from 2 to 6 ft. and 600×1,000 ft. in area has been discovered at the bottom of Loch Lake, Kings County, Nova Scotia. The material is light gray when wet, becoming almost white and very adhesive when dry. Its clay impurities render it unsuitable for use as tripoli. Another deposit occurs in Telegraph Lake in the same locality. Tripolite is produced in Nova Scotia by the Cairo Polishing Co., at River Denny, Inverness County, and the Bass River Infusorial Earth Co., at Bass river, Colchester County, N. S., Canada, where it is found in a bed 3 ft. thick. It is purified by special treatment. The Victoria Tripolite Co., which makes a specialty of insulating material, has commenced extensive exploitation near St. Ann's, Victoria.

county. The tripoli deposit of Fitzgerald Lake, near St. John, New Brunswick, is nearly white after calcination, and an assay gave: Soluble silica, 82% ; insoluble silica in the form of impalpable quartz flour, 17.5% ; clay, iron oxide, etc., traces. The tripoli is covered over by a deposit of grass and peat which is still forming.

*Grindstones.*—The value of the production of grindstones in the United States during 1901 was \$580,703, against a value of \$710,026 for 1900. The value of the imports during 1901 was \$88,871. The amount of pulp stones produced in the United States during 1901 was 860 short tons, valued at \$18,800, as compared with 553 short tons, valued at \$12,495 during 1900. The price per ton decreased from \$26 in 1900 to \$22 in 1901. Pulp stones were produced in 1901 principally from the quarries at Empire, Peninsular, and Tippecanoe, O.

*Pumice.*—There was no output of pumice in the United States during 1901. The mines of the Chicago Pumice Co., in Utah, have been shut down owing to their inability to compete in price with the Lipari pumice, which is exported from Italy to the United States as ballast. A large deposit of pumice is reported from Sonoma County, Cal., and pumice sufficient to supply the demand of this country is found in Hawaii. The pumice industry is principally carried on in the Island of Lipari, Italy, the annual output amounting to about 8,000 metric tons. The pumice mixed with volcanic ash is found in a stratum of from 1 to 4 m. thick, extending over an area of about 6 square miles. It is overlaid by volcanic deposits of various character which have a thickness of from 4 to 8 m. At the present time over 200 mines are in operation, giving employment to 800 persons. As soon as the stone is brought to the surface it is sorted into grades, of which there are 16 recognized by the trade, determined by the size, color, and weight of the lumps. It is then forwarded to Lipari for manufacture.

*Quartz and Flint.*—The output of quartz or flint in the United States during 1901 amounted to 34,420 short tons, valued at \$149,297. Of this total 51.3% was ground by the producers. There was a good demand and an increased price for flint during the year. The output of crude crystalline quartz during 1901 was 14,050 short tons valued at \$41,500, which was used after grinding chiefly in the manufacture, with Japans and oil, of wood filler, although some is sold as tripoli, a considerable amount used as an abrasive in marble cutting, and a limited amount for the production of sandpaper.

French sea flint pebbles are gathered on the beaches between Havre and St. Valery-sur-Somme, a distance of a little over 100 miles. Those which are nearly spherical in shape are carefully selected and are used in the Alsing system of cylinder grinding, which is becoming so generally employed for pulverizing cement, pharmaceutical and chemical products, etc. The others are bought by the potteries for making ordinary porcelain ware, after being calcined, ground into a fine powder, and mixed with china clay. The yearly exports from France are about 13,500 tons, of which nearly one-half goes to the United States. The value of the selected pebbles varies from \$8.52 to \$10.21 per ton, in bags or barrels, f. o. b. at shipping port, while the pottery pebbles range from \$1.27 to \$2.92 per ton, f. o. b. in bulk. Ocean freight from Havre or Dieppe to New York averages 10 fr. (\$1.93) per metric ton. Competition is keen with the Danish and other pebbles that are used for the same purposes.

**Sand.**—The bacteriological efficiency of sand as a filter for water is shown in the results obtained from the large filtration plant at Albany, N. Y. The weekly averages of bacteria in the unfiltered water ranged from 4,733 to 66,000 per c.c. and the percentage of removal ranged from 94·8 to 99·7% ; the former figure was exceptionally low, the next lowest being 97·8%. Slow sand filtration will remove nearly all pathogenic bacteria, but will not remove all coloring matter from the water; the amount of the latter removable ranging from 25 to 50%. Odor is difficult to remove, and the results at Albany were not always effective, the odor being particularly noticeable in waste water from gas works.

PRODUCTION OF WHETSTONES AND SCYTHESTONES IN THE UNITED STATES.

(a) Quantities given for Hindustan, Indiana, Arkansas and Washita stones and miscellaneous oilstones are pounds; for New Hampshire and Vermont scythestones, and Ohio and Michigan grit the quantities are number of gross. (b) Including Queer Creek, Chocolate, etc., estimated. (c) Detailed statistics not available.

**Ferrosilicon.**—The 7,830 calories liberated by ferrosilicon, as against 2,473 calories by carbon, when both are present (1% of either) in iron in process of Bessemerization to steel renders the use of the ferrosilicon in special processes of steel manufacture which deal with small quantities, far preferable to that of carbon alone, as the steel is not brittle unless there is also an excess of carbon. The metallurgical value of ferrosilicon increases with the percentage of silicon present. Ferrosilicon is being manufactured from scrap iron, quartz and coke at Meran, Germany, and at several carbide works in France. The product contains 77·5% Fe and 21·5% Si, and costs at Meran, \$40 per metric ton, the yield in the electric furnace being one ton per 5,000 K.W. hours. The selling price of 10% Si in ferrosilicon is about \$36 per metric ton, and that of 25%, \$60 per metric ton, each 1% additional from \$2 to \$2·40 extra per ton. The use of Martin slags assaying SiO<sub>2</sub> 50·42%, Al<sub>2</sub>O<sub>3</sub> 2·26%, FeO 34·1%, MnO 9·42%, CaO, MgO. etc. 3·3%, when mixed in the proportion of 1,680 kg. of slag and 600 kg. of 80% C. coke, yielded ferrosilicon containing 23·8% Si. There was produced in 110 hours, 4,090 kg. of material with a consumption of 5,380 K. W. hours per metric ton. The mixture used for the manufacture of ferrosilicon in the Styrian blast furnaces at Meran is 1,000 parts of forge iron scales, 410 parts of quartz, and 940 parts of coke. The electric furnaces use 1,000 iron scales, 410 quartz, and 398 coke; the percentages of useful elements in the raw material being Fe 71·9%, SiO<sub>2</sub> 91·3%, C 63·9%.

## SLATE.

THERE was an increase in the production of slate in 1901, the output being 1,304,379 squares of roofing slate, valued at \$4,114,410 and \$673,115 slate manufactures, against 990,036 squares (\$2,885,153) of roofing and \$502,051 of manufactures in 1900. The active demand in foreign markets had a buoyant influence on the industry during 1901, and the promise for 1902 is even better; the domestic trade also showed an increase in volume. The prices obtained for roofing slate were much better than in the preceding year, being more than in 1899, as the producers abided more closely by their established schedule of rates, the average price per square for the entire country being \$3.15, against \$3.01 in 1900, and \$3.14 in 1899.

PRODUCTION OF SLATE IN THE UNITED STATES. (a)

| States.                             | 1900.                         |             |                          |                 | 1901.                         |             |                          |                 |

(a) Not including slate pigment. (b) Peach Bottom included in Pa. (c) Estimated.

**NOTE.**—The production of slate pigment, including Baraga graphite and various kinds of mineral black, in 1900 was 6,617 short tons, valued, after grinding, at \$72,787, against 4,911 (\$50,338) in 1899. In 1901 the quantity of slate pigment produced in the United States is included under amorphous graphite, given elsewhere in this volume.

**Export Trade.**—The value of the roofing slate and slate manufactures exported during 1901 amounted to \$898,262, as compared with \$950,543 in 1900. The greater bulk of the shipments were to the United Kingdom via New York or Philadelphia.

The exports of roofing slate again showed a decrease in value due to the settlement of labor difficulties with the old, and the opening of new quarries in Wales. The exports to Australasia, however, increased, as they have done for several years past, by about 12%. New York, Philadelphia, Baltimore and Boston ports shipped the larger part of the slate exported to Denmark during the year, which country, received roofing slate to the value of \$43,344 in 1901, against \$25,437 in 1900.

value of all kinds of slate being \$62,755 in 1900, against \$100,960 in 1901. The value of the roofing slate quarried in New York varies from \$2 to \$10 per square, the higher figure being caused by the small output of red slate, which is produced in no other State in the country. In 1901 Vermont produced 24.27% of the total slate of the United States during that year. In 1901 the total value was \$1,162,191, an increase of \$244,729 over 1900. The production of roofing slate was 330,191 squares, valued at \$984,317, against 282,820 squares, valued at \$795,474 in 1900. The smaller companies still held their prices through the selling agency established by them in 1900. The introduction of labor saving devices, notably by the Auld & Conger Co., of Cleveland, Ohio, who are the largest operators on the Poultney slate belt, has had much to do with placing the industry on a firm and economical basis. Among the improvements installed by the Auld & Conger Co. is an anchorage for the cables used to haul the slate from the pit. This anchorage consists of a heavily weighted car to which the cable is attached, and which travels on a track shaped to the segment of a circle, thus permitting a range of working of 50 ft. on either side of the normal line of a straight away cable. The saving in time by the use of this device will be appreciated by those who have been compelled to shift the bolthead anchorage of the incline, to accommodate some point perhaps but temporarily needing attention. This company has direct communication with the railroad three miles distant by means of an overhead cable tramway, and its self dumping waste rock rigging and system of providing splitting rock for the slate making sheds permits the most economical handling possible.

*Virginia.*—The output of roofing slate during 1901 was 53,630 squares, valued at \$178,979, against 56,365 squares, valued at \$185,211, a slight decrease in production during the year, but the decrease of 2,735 squares in output was somewhat compensated for by the increased average value per square, which was \$3.33 in 1901, against \$3.28 in 1900.

*New Caledonia.*—The slate deposits at Wagap and Manghine in New Caledonia, are said to be of excellent splitting quality, and the seams are very large.

*Newfoundland.*—The Wilton Grove slate quarry at Smith's Sound was very active in its operations during 1901, with the result that 2,000 tons of slate (equivalent to 6,000 squares) valued at \$22,500 was produced during the year, against 600 tons (equivalent to 1,800 squares), valued at \$10,800 during 1900. All of the 1901 production was exported to England. The slate is made in two sizes, 10×20 in. and 12×24 in., the former size being exported to Newcastle, and the latter to London. A stone steamship pier has been erected on the waterfront, enabling direct shipment of the finished product. About 50 men are employed, and Ingersoll steam drills are in use, the slabs being hoisted from the quarry by derricks. The slate is largely a dark purple in color, but some sea-green is also found. Several new deposits were located during the year.

*United Kingdom.*—The total quantity of slate produced in the United Kingdom during 1900 was 585,859 tons (about 1,757,577 squares), valued at \$7,336,613, of which all but about 10% was consumed in the United Kingdom, beside the large importation from Newfoundland and the United States.

and bleaching powder by the electrolysis of fused salt. It is reported that have had some difficulty with the bleach produced, but that they have now arrangements by which these difficulties will be overcome. The Castner electrolytic Alkali Co., at Niagara Falls, has had under way during the year an enlargement of its plant which will enable it to use 6,000 H.P. in production of caustic soda and bleach. Its first installation, which has been in operation for about two years, utilized 2,000 H.P. It is expected that the additional plant will begin producing in the latter half of 1902. The Pennsylvania Salt Manufacturing Co. has purchased land on the Detroit river, near the mouth of the Michigan Alkali Co., at Wyandotte. On this property, which has a large river frontage, it is erecting an electrolytic plant for the production of caustic soda and bleach. The company has acquired American rights in the patents granted to George Bell and George W. Bell, of Liverpool. It is said that they expect to turn out 100 tons of caustic and 150 tons of bleaching powder weekly, and if the venture is successful four similar units will be added. There has been a continuance during the year of the increased output of natural soda in the West, and it is estimated that during 1901 there was produced from this source 900,000 tons of soda in its various forms. The Occidental Alkali Co., of Hawthorne, Nev., which produced a small quantity of natural sodium carbonate salt during 1900, made no production during 1901. In addition to the production of soda products mentioned above, there was imported from English makers approximately 15,000 tons of soda products on a basis of 58% in the forms of caustic, bicarbonate and sal soda. This, as will be seen, is a radical reduction in imports from the year before. Furthermore, there has been a small export of soda products from this country to various points, notably to Great Britain. Exports have not been of any considerable quantity and have tended to decrease in the latter part of the year. It is thought that there was not sufficient profit in the business to make it attractive.

## IMPORTS OF SODA PRODUCTS INTO THE UNITED STATES.

|                  | 1897.       |              | 1898.       |              | 1899.       |              | 1900.       |              | 1901.       |              |

(a) Including sal soda. (b) Included in other soda salts.

**Market Conditions.**—The average monthly price of domestic 58% ash per b. in lots of 50 tons or more f. o. b. works, is given in the following table:—

| Year. | Jan.  | Feb.  | Mch.  | April. | May.  | June. | July. | Aug.  | Sept. | Oct.  | Nov.  | Dec.  | Average. |
|-------|-------|-------|-------|--------|-------|-------|-------|-------|-------|-------|-------|-------|----------|
| 1897. | 53.75 | 51.25 | 53.75 | 50.50  | 57.50 | 57.50 | 51.50 | 52.50 | 50.00 | 50.00 | 57.50 | 57.50 | 54.35    |
| 1898. | 57.50 | 59.20 | 62.50 | 66.50  | 67.50 | 68.75 | 68.75 | 70.00 | 71.75 | 80.00 | 82.50 | 83.50 | 69.45    |
| 1899. | 86.66 | 87.50 | 87.50 | 82.50  | 82.50 | 82.50 | 82.50 | 82.50 | 77.50 | 77.50 | 72.50 | 75.50 | 81.43    |
| 1900. | 80.00 | 80.00 | 74.00 | 80.00  | 78.75 | 77.50 | 80.00 | 76.50 | 75.50 | 77.50 | 78.50 | 85.00 | 78.60    |

Domestic bicarbonate of soda sold at 95c.@\$1.10 per 100 lb. f. o. b. works, as compared with \$1.065@\$1.375 in the previous year. Extra grades remained unchanged at \$3.25@\$3.50 per 100 lb. f. o. b. works, less the usual discounts. Foreign ordinary grades brought \$1.375@\$1.75 per 100 lb. in New York.

Domestic caustic soda sold at \$1.70@\$1.95 per 100 lb. f. o. b. works, while foreign brought \$1.85@\$2.50 per 100 lb. in New York. Contracts for 1902 and 1903 were made at \$1.85@\$1.925 f. o. b. works. There was a good sale for this article among glass makers and mercerized goods manufacturers, but the imports were considerably less than in the preceding year.

Domestic soda ash in bags sold at 70@85c. per 100 lb. f. o. b. works for 58%, and 80@90c. for 48%. The market showed more strength in the latter part of the year owing to the destruction by fire of the plant owned by the Michigan Alkali Works and also to the depletion of stocks. Foreign soda ash was quoted at 85@87.5c. per 100 lb. in New York.

Domestic sal soda was quoted at 50@55c. per 100 lb. f. o. b. works in the East, and foreign at 65@67.5c. in New York. These prices are much lower than those ruling in 1900, the decline being caused by the competition among manufacturers, although the imports were less.

Bleaching powder of domestic make was quoted on the basis of the prices ruling for imported material, which were \$2 for prime Liverpool and \$1.75@\$1.875 for Continental brands on contracts. New contracts for 1902 were made in the last quarter of 1901 at \$1.75@\$1.90 for prime Liverpool, and \$1.70@\$1.85 for Continental makes.

*Natural Sodium Carbonate.*—The production of natural sodium bicarbonate reduced to a basis of 58% ash during 1901 was about 15,000 short tons (\$197,000), as against 14,100 short tons (\$195,300) in 1900. The production continues to come from California and Nevada.

*Sodium and Potassium Chlorates and Hypochlorites.*—A review of these industries during 1901 is given under the caption "Potash and Potassium Salts," elsewhere in this volume.

*Sodium Nitrate.—Chile Salt-peter.*—The production of sodium nitrate in Chile during 1901 was 1,417,806 long tons, as compared with 1,473,091 long tons in 1900, a decrease of 55,285 long tons due to the rigid restriction of output by an agreement dated April 1, 1901, entered into by the principal producers. The combination on April 1, 1901, allotted the production for the year ending March 31, 1902, on an exportation of 31,273,000 quintals, with a subsequent agreement that but 75% of this amount should be exported during the succeeding 9 months. Good dividends were paid during the year by many oficinas, due to the utilization of the costras, ripios, and cuevas caliche formerly wasted. The cost of production has, however, decreased but little, due to the extra care taken with shipments. The report of the Salar del Carmen Nitrate Syndicate for the year ending December 31, 1901, is as follows: Gross receipts, £47,320 (\$236,600), showing an increase of over 37%, as compared with 1900. After providing for the debenture interest and redemption account there was a surplus of £26,076 (\$130,380). A dividend of 10% has been paid and £15,000 (\$75,000) carried to reserve account, while £3,000 (\$15,000) has been written

for depreciation of plant. The output of the plant was again fixed at 1,000 quintals, and according to the report the cost of production should not exceed 4s. 8d. (\$1.12) per quintal. It is estimated that the small nitrate companies averaged profits of from 24 to 42c. per quintal (about from \$5.15 to 18 per long ton) during 1901, while the larger companies, with more opportunity for economy, earned larger dividends proportionately. A description of the Chilean sodium nitrate industry may be found in *THE MINERAL INDUSTRY*, I. IX., p. 596, *et seq.*

**Sodium.**—There are several works manufacturing metallic sodium in the United States, among them the Niagara Electro-Chemical Co., of Niagara Falls, N. Y., but no statistics of production are available. It is reported that several tons per week of potassium cyanide are manufactured at Niagara Falls by means of metallic sodium. Sodium peroxide in quantity is also manufactured at Niagara Falls, N. Y.

#### THE IMPROVED AMMONIUM CHLORIDE DISTILLER FOR A 100-TON SODA ASH PLANT.

BY JOHN R. WATSON.

THE distillers for the production of ammonium from ammonium chloride liquors in ammonia soda works vary considerably in detail, though in principle they are much the same.

The original design of an efficient ammonium chloride liquor distiller must be credited to Dr. Ludwig Mond, and the improved apparatus shown in the illustration, Fig. 1, on the following page, is a development of the type described in *Lunge's Sulphuric Acid and Alkali*, Vol. III., p. 111.

The most important improvements have been made along the following lines:—

1. In the proportion of the areas of the component parts.
2. In the distribution of the descending liquors.
3. In the form of the distiller portion, which comprises the lower compartments Nos. 1 to 11.
- In the form of the diaphragm plates, and
- In the location of the inlet and outlet pipes.

While all of these improvements have resulted in a very efficient apparatus, perhaps the one of most importance is the better location of the inlet and outlet pipes. The diaphragm plates, as shown in the cross section, Fig. 1, are in the form of an ellipse, which have proven the most satisfactory of all the various forms used. The scale in the compartments assumes this shape. Total height is 91 ft. Considering the requirements to be fulfilled in the distiller in which the ascending gases travel in a direction opposite to the descending liquor, a good way to ascertain the proper area of the gas passages above the diaphragm plates and between them and the hood plate, is that each area shall be at least three times the area of the gas passage, and that the diameter of the hood plate at the point of denticulation shall be at least 70% of the diameter of the distiller. It should also be noted that the heater compartments of the distiller, shown in the illustration by Roman numerals I to XX, are of what may be termed the "bubble and spray" type. In all there are 33 compartments.

FIG. 1 DISTILLER FOR AMMONIUM CHLORIDE LIQUOR

The object in the upper compartments of the apparatus is to offer a minimum resistance to the ascending gas, and at the same time to split up the descending liquors as finely as possible. This is attained by having the denticulations of the corona plates finished off to a knife edge, the denticulations acting as distributors. The descending liquor then takes the form of a thin veil, which is broken through by the ascending gases. The lower portion of the heater is of the "bubble" type, which offers a greater resistance but brings the ascending gases into closer contact, at the same time the liquor is heated to a greater extent than could be done with a spray. It should be noted that the depth of the liquor or the seal over the perforations in the bubble plates should never exceed 3.5 in. If these dimensions are exceeded to any great extent, the resistance to the passage of hot ascending gases materially affects the economical working, and also increases the back pressure on the exhaust steam used in the distiller. A heater of this type is operated under a partial vacuum of from 2.5 in. to 7 in. of mercury.

The following table gives the results obtained in the practical working of the distiller. The determinations for free ammonia were made on samples of 20 c.c. each of solutions taken from the several compartments, while those for combined ammonia were made on samples of 200 c.c. each.

| Distiller.          |                                    |                                                  |                 |                 | Heater.             |                                    |                                                  |                 |                 |

| 10.....             | 20.6                               | 157.5                                            | 5.7             | 96              |                     |                                    |                                                  |                 |                 |
| 11.....             | 39.9                               | 352.0                                            | 5.4             | 88              |                     |                                    |                                                  |                 |                 |

The working of a distiller is continuous for four or five weeks, and consists in admitting the ammonium chloride liquors, or what is termed "filter liquors," to the top of the heater. During the descent the free ammonia is expelled while the combined ammonia is not driven off until the distiller portion of the apparatus is reached, where in contact with milk of lime it is liberated. Usually exhaust steam at from 15 to 20 lb. pressure is admitted at the bottom, as shown in the illustration. The waste lime is blown off from the bottom compartment.

In order to obtain the maximum efficiency for the distiller, the following factors of working must be carefully regulated:—

1. The temperature of the incoming liquor at the top, also that of the heater portion of the apparatus and of the outgoing gases.
2. The strength of the vacuum at the top of the heater.
3. The amount of lime and salt in the blow-off liquors.
4. The amount of free and combined ammonia in the incoming liquor and in the blow-off liquor (tested every 15 minutes).

The distiller described above will handle all the return ammonium chloride liquors for a plant producing 100 tons soda ash per day.

## STONE.

THE leading varieties of stone produced in the United States in the order of their importance are limestone, granite, sandstone, marble and slate. Detailed information as to the important quarrying centers, character of their output, and the relative value of stones for different uses, will be found in THE MINERAL INDUSTRY, Vol. VIII. Slate is treated separately elsewhere in this volume.

The total value of the stone produced in the United States during 1901 amounted to \$55,488,137, against \$45,066,708 in 1900; neither of which totals includes the sandstone used in the manufacture of grindstones and whetstones, which is included under silica, and are also exclusive of the value of the production of slate, both of which may be found in detail elsewhere in this volume.

The value of the imports and exports of stone into the United States for the fiscal year ending June 30, 1901, was \$1,276,602 and \$774,614, respectively, the former inclusive and the latter exclusive of the respective values of slate.

*Limestone.*—The value of the total production during 1901 was \$26,406,897, the value of that used for building being \$5,219,310, including \$404,163 for railroad bridges; for railroad ballast, \$1,758,541; for macadam, \$2,298,286; for concrete, \$1,214,815; for riprap and rubble, \$1,024,109; for the production of lime, \$8,204,054; for blast furnace flux, \$4,659,836, and for the limestone used in the manufacture of Portland cement, \$570,882. The principal producers rank in the order of maximum production as: Pennsylvania, with a production valued at \$5,081,387 for 1901; Illinois, \$2,793,837; Indiana, \$2,993,186; Ohio, \$2,606,502; New York, \$1,738,716; Missouri, \$1,362,272; Wisconsin, \$1,225,448.

*Granite.*—The total value of the granite produced during 1901 amounted to \$15,976,971, which includes that used for concrete, \$477,709; for road making, \$2,008,966; and for railroad ballast, \$516,768; for curbing and flagging, \$670,703; riprap and rubble, \$1,755,959; sold in the rough, \$3,486,574, for paving blocks, \$1,821,431; and for dressed building stone sold by the producers, \$3,781,294. The principal States rank in the order of their maximum production as: Maine, \$2,703,116; Massachusetts, \$2,216,258; Vermont, \$1,245,828; California, \$1,134,675; South Carolina, \$996,084, and New Hampshire, \$935,494.

*Sandstone.*—The total value of the production during 1901 was \$8,844,978, of which was used for building purposes, \$4,875,973; for railroad ballast, \$30,887; for road making, \$130,503; for concrete, \$123,957; for paving, \$358,910; for riprap and rubble, \$447,520; for curbing, \$636,722; for flagstones, \$1,026,499; for other purposes, including grind and whetstones, \$1,214,007. The principal producing States rank in the order of production as: Ohio, with a total production valued at \$2,576,723; Pennsylvania, \$2,063,082; and New York, \$1,331,327.

*Marble.*—The total value of the marble produced during 1901 was \$4,965,699, of which that used for building purposes was \$1,236,023; for ornamental work, \$126,576; sold in the rough, \$591,667; for interior work, \$1,008,482, and for cemetery work, \$1,948,892.

## SULPHUR AND PYRITES.

THE production of sulphur in the United States during 1901 was 6,866 long tons, valued at \$223,430, as compared with 4,630 long tons in 1900. The output of the States in the order of importance was: Nevada, Idaho, Utah and Louisiana. The total quantity of sulphur produced in the United States has always been of insignificant proportions, as compared with the total consumption. More than 1,000 tons of sulphur, including the sulphur content of pyrites are consumed annually in the manufacture of sulphuric acid.

### SULPHUR PRODUCTION, IMPORTS, AND CONSUMPTION IN THE UNITED STATES.

| ..... | 862            | 11,551         | 123     | 1,445   | 891     | 544,119       | 14,435 | (e)     | 750    | 70     | 4,704          |

(a) From the official reports of the respective governments. The sulphur recovered as a by-product by the *soc-Claus process* in the United Kingdom, amounting to about 31,000 long tons in 1898 is not included. (b) Crude. (c) Raw mineral; limestone impregnated with sulphur. (d) Crude rock. (e) Statistics not yet published.

*Australasia.*—During 1900 there were produced 1,692 long tons of sulphur in New Zealand, the product being consumed by the sulphuric acid makers of the State.

*Chile.*—The sulphur deposits at Taltal are being actively worked by a native company. It is reported that 60 men were employed during 1901. A company capitalized at \$40,000 has been formed at Iquique to exploit the sulphur deposits in that vicinity, the product to be utilized at the nitrate works in Tarapaca and Atacama in the manufacture of blasting powder and in the extraction of iodine. The deposits are at an elevation of 3,500 or 4,000 m. and can only be worked during the summer months—from October to April. The location renders it very costly to transport the material to the railroad terminus, although the air-line distance is only 80 km.

*Canada.*—A large deposit of sulphur is reported to have been found on the Skeena river, B. C., and arrangements are being perfected to exploit the property with the view of shipping the product to Victoria and other Sound ports.

*Greece.*—Sulphur is found on the Island of Milos at Phyrilaka and Tsakistras as impregnations in weathered trachyte and at Phirlingos as irregular masses in porous sandstone (millstone). The earthy sulphur of Phyrilaka is used principally in grape culture, while the hard ores of Phirlingos are treated in distillation furnaces. At present there are five furnaces in operation all owned by La Société des Naux Publiques et Communaux, and the annual production amounts to about 1,000 tons, which is consumed in the manufacture of sulphuric acid.

*Italy.*—The Trabonella Sulphur mines have recently been equipped with complete modern mining machinery. The old pillar method has been supplanted by the long wall system. A 600-H.P. Dawson gas engine motor driving six electric motors furnished light and power. Hoisting is accomplished by a 60-H.P. three-phase motor, giving a speed of 4.2 per second with an unbalanced load of 2,375 kg. A conical drum and a two-deck cage are used. Rich deposits of sulphur have been reported in the Comitini district, at the Cannarella mine near Castrogiovanni, and in the Agira district. It is reported that prospecting operations have been carried on satisfactorily.

(a) From report of A. S. Malcomson, New York. (b) Includes exports to Denmark.

The Anglo-Sicilian Sulphur Co., with an authorized capitalization of \$35,000, of which £607,200 has been issued, reports for the fiscal year ending July 31, 1901, a net profit of £106,644, after placing £8,500 to the reserve fund. Dividends to the extent of £34,335 were paid, and £36,403 was credited to the general reserve fund, which is now £119,245. This, with the capital guarantee fund, provides a reserve of £171,620, exclusive of £36,529 which has been set aside for depreciation of stocks of sulphur. The company renewed the contracts with Sicilian sulphur producers for 5 years from July 31, 1902.

*Japan.*—The production of sulphur in Japan during 1900 amounted to 35 tons, valued at £31,000. The output was derived mainly from the provinces of Hokkaido, Rikuzen, Asumi and Shenaro. The imports of Japanese sulphur into the United States during 1901 amounted to 10,705 long tons, valued at \$206,899.

*Russia.*—Sulphur deposits have been reported near Damba and Shük, on the road to Askahbad (Kara-Kum), as well as in the vicinity of Kukurtinsk, between the railroad stations of Balla Ishem and Mulla Kara. During the last few years some several thousand tons of sulphur were obtained from the Kara-Kum district. A Belgian syndicate is about to exploit these deposits on a large scale.

*Venezuela.*—The German Venezuelan Sulphur Co., with a capital of 2,000,000 marks (\$476,000), is actively at work setting up the aerial cable by which the sulphur will be carried from the mine, near Carupano, to the port, a distance of about 18 km. The landing wharf is finished and the managers await only the termination of the wire-rope railroad to begin loading on a large scale.

## PYRITES.

The production of pyrites in the United States during 1901 was 234,825 tons (\$1,024,449), as compared with 201,307 long tons (\$684,478) in 1900. In spite of this large increase the demands were far in excess of all records. It seems out of the question materially to increase the tonnage mined in the United States, and as there have been no new developments of properties nor increased developments of mines in Massachusetts, Virginia and Georgia,

the condition exists that foreign pyrites must be consumed in a greater proportion than ever before. This means that the prices will be steadied to a point where it will become possible to open up new sources of pyrites to meet the greater demands for manufacture of fertilizers, the refining of oils and general chemical use.

The most available supply of sulphur at present and most generally distributed over the country where consumption of acids is greatest is the zinciferous sulphur ores of Arkansas, Missouri, Kentucky, Kansas and other States. Millions of tons of these ores are obtainable and can be brought to common centers for extraction of their sulphur content, yet up to the present time only three plants have been established for this purpose, viz.: at Peru and Peoria, Ill., and at Argentine, Kan. By the use of specially constructed mechanical furnaces it is possible to save from 25 to 28% of the sulphur in these ores, bringing the cinders down to about 2% S, and a subsequent roasting in a Falding or Chase furnace will fit the material for extraction of the zinc by cheap methods. The coming year promises the installation of other roasting plants, so that doubtless the tonnage of sulphur from pyrites will be largely augmented by the utilization of the sulphur from zinc sulphides, thus keeping the balance between domestic and foreign sulphur ores to its present ratio.

The industrial activity of the United States is responsible for the enormously increased demand for sulphuric acid, and it is not difficult to prognosticate that should prices remain normal as at present, within a few years the demand for sulphuric acid of inland consumers will be supplied in a large part from domestic zinc and other sulphide ores.

The largest consumers of sulphuric acid,—the Virginia-Carolina Chemical Co., the American Agricultural Co. and the Standard Oil Co.,—now purchase ores, from which the acid is manufactured. Fully 90% of all the acid manufactured in the United States is required for the different uses of these corporations.

The purchase in the United States of all domestic and foreign pyrites and other ores used for the sulphur content is practically in the hands of four trade combinations, and as the total purchases amount to approximately 500,000 tons annually, stocks of foreign ores can be accumulated at the seaboard and shipped inland in quantities to secure lowest freight rates; the importation of foreign ores is favored and but little incentive is left to develop domestic mines of uncertain character.

PRODUCTION, IMPORTS AND CONSUMPTION OF PYRITES IN THE UNITED STATES. (a)  
(IN TONS OF 2,240 LB.)

| Year.     | Production. |           | Imports. |     |           | Consumption. |             |
|-----------|-------------|-----------|----------|-----|-----------|--------------|-------------|
|           |             |           |          |     |           |              |             |
| 1897..... | 133,368     | \$404,690 | 259,546  | 47% | \$847,419 | 392,914      | \$1,232,115 |
| 1898..... | 191,160     | 589,329   | 171,879  | 47% | 544,165   | 363,039      | 1,135,494   |
| 1899..... | 178,408     | 583,323   | 310,006  | 47% | 1,074,855 | 468,416      | 1,543,178   |
| 1900..... | 201,317     | 684,478   | 329,449  | 47% | 1,089,693 | 530,766      | 1,774,171   |
| 1901..... | 234,825     | 1,024,449 | 403,706  | 47% | 1,415,149 | 636,531      | 2,450,598   |

(a) These statistics do not include the auriferous pyrites used for the manufacture of sulphuric acid in Colorado.

*Market.*—The heavy consumption of pyrites by makers of sulphuric acid for

fertilizer trade favored an increased domestic production and larger imports in 1900. Prices were firm as the important consumers make season contracts advance. In Virginia producers quoted f. o. b. Mineral City \$4.90 per long ton for lump ore, and \$4.20 for fines (basis 42% S). Massachusetts miners quoted f. o. b. Charlemont \$5.50 for lump ore, and \$4.75 for fines. A prominent importer at New York contracted for the output of some Spanish mines and subsequently made good-sized contracts with consumers in the United States. The ocean freight from Huelva, the leading shipping port in Spain, fluctuated between \$1.92 and \$2.34 per ton to Atlantic ports. Spanish pyrites sold here at 12@14c. per unit of sulphur. The imports of Spanish and other pyrites into the United States in 1901 totaled 403,706 long tons, as against 9,449 tons in 1900.

*Georgia.*—The Durgey property, near Villa Rica, owned by the Virginia-Georgia Chemical Co., has been brought to the producing stage and promises to be a steady shipper of high-grade pyrites. There are several prospects which have been developed more or less, one of them in Harrelson County,—the Gamble mine,—and one of them in Carroll County, from which several thousand tons have been raised to the surface, but no shipments of consequence have been made. *Massachusetts.*—The Davis mine was the only producer and has kept up its record for steady shipments and uniform products. All this ore is marketed near home, and in this respect it is and has been an exceedingly favorable mine proposition.

*New York.*—(By W. H. Adams.)—The Stella mine, at De Kalb Junction, is a producer for only a few months during the year. The deposits were opened only to supply the actual demands up to the time when the mine was closed. The shipments were about equal in tonnage, the lump ore averaging about 35% and concentrates averaging about 48% S. The machinery is not up to modern requirements, and this property, a very promising one, deserves development and working on a large scale. Every ton to be produced from this mine can be marketed within a short distance, and there is a constantly growing trade connected with sulphite pulp mills which could be handled from this location.

*Virginia.*—(By W. H. Adams.)—The Arminius Chemical Co., the Pyrites Mining & Chemical Co., and the Sulphur Mineral & Railroad Co. operated the mines in Louisa County during 1901 and, with the Detrick mines, near Quantico, in Prince William County, produced about 145,000 tons.

*Domestic Consumption of Sulphur and Pyrites.*—The use of iron pyrite as raw material in place of sulphur for the manufacture of sulphuric acid continues to increase steadily. By far the greater part of the sulphur consumed in the United States is used in the manufacture of paper stock by the sulphite process. The wood pulp is digested under pressure with sulphurous acid or acid sulphite of calcium and magnesium, which, reacting upon the lignin and other incrusting material of the fiber, transforms them into soluble products which are subsequently removed in the liquor.

The increased use of pyrites for acid making has been due very largely to the development of the sulphite wood-pulp industry for the manufacture of paper in which sulphur is used. There is but one sulphite mill in the United

States using pyrite in place of sulphur in the treatment of wood pulp, although in Europe a considerable quantity of pyrite is utilized for this purpose. Another important factor has been the increased production of phosphate rock from Florida and Tennessee and the domestic manufacture of superphosphates. For these purposes a chemically pure sulphuric acid is not essential, and that made from pyrite serves the purpose equally as well as that made from sulphur.

CONSUMPTION OF SULPHUR IN THE UNITED STATES. (IN TONS OF 2,240 LB.)

## PROGRESS IN THE SULPHURIC ACID INDUSTRY DURING 1901.

BY F. J. FALDING.

THE year 1901 has been characterized not so much by any startling novelty in the manufacture of sulphuric acid as by earnest work looking to the improvement of the technique, both of the old chamber process and the contact process.

In Germany, exceedingly important papers have been published, the one a masterly treatment of the manufacture of sulphuric acid by the contact process,

Rudolf Kneitsch,<sup>1</sup> of the staff of the Badische Anilin und Soda Fabrik, which is given in full detail later in this section; another, by Fr. Luty and H. H. Nienfuhr,<sup>2</sup> being a discussion of the comparative costs of production of sulphuric acid by the contact process and modern lead chamber processes; also one by Dr. Theo. Meyer, on "The Reform of the Chamber Processes."<sup>3</sup>

In France, L. Pierron has supplemented his valuable report to the International Congress of Applied Science, of Paris, fully quoted in *THE MINERAL INDUSTRY*, Vol. IX., by a special paper relating to the manufacture of sulphuric acid by the contact process.<sup>4</sup>

These interesting papers are so remarkable for careful thought and so frank in their disclosures of the results of costly and laborious experiment and experience as to make the year remarkable if nothing else had been done.

*The Contact Process.*—Dr. Kneitsch, by means of an examination of the history of the contact process, shows how failure followed failure until the quantitative conversion of sulphurous into sulphuric acid was regarded as absolutely hopeless; how finally "the surprising discovery was made that there are substances which can even in exceedingly minute quantities diminish the catalytic action of the platinum to an extraordinary extent." He further states that "the harmful action of arsenic alone, for example, was found to be so great that even quantities amounting to only from 1 to 2% of the platinum contained in the contact mass it sufficed to render it entirely inactive." Even with this certain knowledge of the cause of failure, success still seemed to be hopeless, as at that time the entire removal of the arsenical fumes from the burner gas was considered technically impossible. Finally after years of "enormous expenditure of time, trouble, money and patience, experiment following experiment, the solution of the problem was found," so that now it is "quite possible to rid the burner gas completely of all its impurities by subjecting it, after suitable treatment and cooling to a systematic and continued intimate contact with water or sulphuric acid. The manner in which the intimate contact with purifying liquids is obtained is a matter of indifference so far as the final result is concerned. For example, extensive washing and moist filtration alone or in combination are found to be equally effective."

Dr. Kneitsch states here that after the complete purification of the burner gas it seemed to have been arrived at a gradual deterioration of the contact mass still

<sup>1</sup> *Berichte der Deutschen Chemischen Gesellschaft*, No. 17, Dec. 28, 1901.

<sup>2</sup> *Zeitschrift fuer Angewandte Chemie*, No. 11, March 18, 1902.

<sup>3</sup> *Zur Reform des Bleikammer processes*, *Zeitschrift fuer Angewandte Chemie*, No. 50, 1901.

<sup>4</sup> "La Fabrication de l'Acide Sulfurique" (Hist. des procédés par contact), *Revue de Chimie Industrielle* Vol. XIII., No. 148, April, 1902.

took place. This was at last found to be due to the action of the acid formed in the cast-iron cooling pipes by which small quantities of arsine ( $\text{As}_3\text{H}$ ) were formed. After the cooling pipes were protected from the action of the acid "the activity of the contact mass remained unchanged." Dr. Kneitsch also states that there is not the least difficulty in obtaining a quantitative conversion of  $\text{SO}_2$  into  $\text{SO}_3$  without pressure of any kind; a fact of great importance in practice.

With regard to the absorption of the  $\text{SO}_3$  Dr. Kneitsch states the remarkable fact that only sulphuric acid of from 97 to 98%  $\text{H}_2\text{SO}_4$  will absorb  $\text{SO}_3$  instantly and completely. His researches into the action upon iron of sulphuric acid of various strengths are technically invaluable—to use his own words: "on these observations we have based a method for the production of sulphuric acid almost absolutely free from iron." Probably, however, the most interesting part of the result of experiments recorded is that relating to the temperature at which the contact reaction takes place. On heating the contact oven containing platinized asbestos the rapidity of the reaction increases, so that at from 380 to 400°C. nearly all the  $\text{SO}_2$  is found to be converted into  $\text{SO}_3$ . From 400 to 430°C. the reaction remains nearly uniformly quantitative, a conversion of 98 to 99% being maintained. From this point the curve falls, but not as rapidly as it rose before. At 700 to 750°C. only about 60% of the  $\text{SO}_2$  is converted, and at 900 to 1,000°C. no reaction can any longer be detected. After describing various experiments, Dr. Kneitsch states: "As the important result of these experiments we have found, then, a line of stable equilibriums which divides the whole range of temperatures into two divisions. Temperatures below 200°C. and above 900 to 1,000°C. may be regarded as resulting in no technical reaction; between 200 and 450°C. the formative reaction preponderates, while above this the decomposition of the sulphuric anhydride rapidly becomes prominent. From these facts important technical conclusions can be drawn; for, even if the boundary line has been determined for one particular technical gas mixture, the various modifications occurring in practice will scarcely have a very great influence in the position of this stable equilibrium. Further, it is evident that this temperature boundary line must be, theoretically and practically, independent of the kind of contact material, from which it follows that only such contact substances will be capable of bringing about an approximately quantitative reaction in a single operation as have their highest activity at the temperature of the zone of formation, that is, under about 450°C. All contact substances that develop their maximum power only beyond this temperature will never be able to bring about a quantitative yield, however long they remained in contact with the gases. At present there is only one contact substance which fulfils these conditions, namely, platinum; nor can this be replaced by any of the other metals of the platinum group, even with approximately good results."

Dr. Kneitsch adds the following statement of the yearly growth of the manufacture of sulphuric acid in terms of sulphuric anhydride at the works of the Badische Anilin und Soda Fabrik: 1888, 18,500 tons of  $\text{SO}_3$ ; 1894, 39,000 tons; 1899, 89,600 tons; 1900, 116,000 tons. Dr. Kneitsch also gives some hitherto unpublished and very precise and complete descriptions of the physical and chemical properties of different strengths of sulphuric acid.

In connection with Dr. Kneitsch's statement regarding the reaction temperature and the line of stable equilibrium of  $\text{SO}_3$  and his conclusion that platinum contact mass is the only contact substance "capable of bringing about an approximately quantitative reaction in a single operation," it is interesting to read Pierron's conclusions on the subject of the technical production of sulphuric anhydride.

"There is a difference of opinion amongst technical men on the subject of the *modus operandi* of obtaining the most economical results. The object being to convert the greatest possible quantity of  $\text{SO}_2$  into sulphuric acid. There are two methods which can be used:—

"First, to regulate the temperature of the contact oven in such a way that only very small quantity of  $\text{SO}_2$  will escape unconverted.

"Second, to follow the ordinary contact oven (from which a considerable quantity of  $\text{SO}_2$  is allowed to escape unconverted) by one or more contact ovens in series in which the  $\text{SO}_2$  escaping from the first oven is converted into  $\text{SO}_3$ . These secondary ovens can either contain the same contact substance or substances having a different contact action."

This last plan, *i.e.*, the combination of several ovens in series has recently been recognized as technically the most practical, as is proved by the fact that certain concerns such as the Verein Chemische Fabrik Mannheim, The Badische Anilin und Soda Fabrik, Meister Lucius und Bruning after having in their early patents treated the operation as complete in a single catalytic reaction, have in their recent patents described the use of a series of apparatus as being advantageous.

The four contact plants erected early in 1901 under the Grillo-Schroeder patent,<sup>5</sup> after meeting with difficulties natural to new processes and novel and untried conditions, are stated to be working regularly and producing a satisfactory yield of acid. Other works are about to be established. Of these four plants one is using the waste gas from roasting zinc blende; two are using arsenical Spanish fines, and one highly arsenical gold and silver concentrates. It is not necessary to say that more difficult raw materials to handle could not well have been selected, and the ultimate success of these plants therefore is all the more satisfactory.

A steady improvement has been made especially in Germany in the various parts of the chamber plant, especially in the accuracy of details tending to secure a complete functioning of the various apparatus. This is notably the case in the packing of the Gay-Lussac, Glover and intermediate towers and surface condensers, as also in the pumping and acid distributing arrangements and all details of construction and operation which tend to reduce the size of the apparatus and to secure a maximum production at a minimum of cost.

The Meyer-Tangential chamber system, mentioned last year<sup>6</sup> as being in operation at Harburg and Rensberg, in Germany, is now in operation in the United States at the works of Griffith & Boyd, in Baltimore, Md.

I regard this system not only as being rational but also as being the first and only distinct advance in construction of the lead chamber proper. As erected

<sup>5</sup> THE MINERAL INDUSTRY, Vol. IX., p. 617.

<sup>6</sup> *Ibid.*, p. 618.

in Baltimore, with the exception of some cooling pipes inserted into the roof of the first chamber, these chambers are perfectly plain and without any adventitious aid such as fans, surface condensers, etc. The system consists of a set of lump burners, Glover tower—three cylindrical chambers 30 ft. diameter by 34 ft. high with tangential gas connections at the upper periphery and bottom central outlet with a small preliminary cooling tower, and final Gay-Lussac tower. During the summer weather these chambers are working at the rate of not less than 10 and not more than 11 cu. ft. of space to 1 lb. of sulphur burned; the yield is excellent, and while at this particular plant the consumption of nitrate of soda is too high, both the results obtained in this respect in Germany and the rational of the process would tend to show that such high consumption of nitrate of soda is unnecessary and is due either to some defect in construction or operation. When it is considered that to approach or equal these results either the skill-management necessary for "marche intensive" or costly apparatus such as fan-surface condensers or Lunge intermediate towers must be made use of, the economy of construction becomes evident with a consequent economy of land, buildings, repairs, amortization and interest. On the other hand if this system were used in connection with the above appurtenances it is difficult to surmise just what the output of such a plant would become.

The most recent proposition for the manufacture of sulphuric acid is that of C. B. Jacobs,<sup>7</sup> assignor to the Ampere Electro-Chemical Co., of Jersey City, N. J.

Mr. C. P. Townsend<sup>8</sup> states that "Faraday and a host of subsequent experimenters have investigated the electrolytic oxidation of sulphur dioxide in aqueous solution, and have found that under normal conditions one-half the oxide undergoes oxidation to sulphuric acid at the anode, the remainder appearing as sulphur or hydrogen sulphide at the cathode. In 1895, however, Dr. Leonard Wael succeeded in rendering the oxidation quantitative by the concurrent use or production of carriers of oxygen, such as the persulphates, or even the halogens. Mr. Charles B. Jacobs now finds that the same result may be accomplished by a judicious application of the principle that oxidation is facilitated by a concentrated solution and low current density at the anode. In Jacobs' apparatus the anode is a porous composition through which the gas is injected in a continuous stream into the cell; and the anode area is 33 times that of the cathode. The apparatus used the vessel is provided with horizontal electrodes and an interposed diaphragm. The porous anode constitutes a partition near the base of the cell, and into the lower compartment so formed sulphur dioxide is injected through the pipe, passing through the previous anode and undergoing oxidation therein. An outlet is provided for withdrawal of the sulphuric acid when a hydrometer shall indicate that the desired density has been reached. A refrigerating jacket is provided in order that advantage may be taken of the increased solubility of sulphur dioxide at 0°C.

"Jacobs, like Wacker, finds that by continuously injecting sulphur dioxide, sulphuric acid may be brought to standard concentration. The electrolytic efficiency is given as 54%, with a potential difference of two volts and a current density of 15 to 20 amperes per sq. ft. of anode surface."

<sup>7</sup> United States Patent No. 704,831, 1902.

<sup>8</sup> *Electrical World and Engineer.*

The following tables have been compiled and calculated by Mr. F. J. Falding from the tables of the United States Manufacturing Chemists' Association and other authorities.

GERSTER'S FORMULA FOR MIXING A STRONG SOLUTION OF SO<sub>3</sub> WITH A WEAK SOLUTION OF SO<sub>3</sub> TO PRODUCE AN INTERMEDIATE SOLUTION OF SO<sub>3</sub> OF ANY DESIRED STRENGTH.

$$X = 100 \frac{b-a}{a-c}$$

When X = quantity of weak solution required to mix with 100 parts of the strong solution.

a = total SO<sub>3</sub> in 100 parts of the solution desired; b = total SO<sub>3</sub> in 100 parts of the strong solution; c = total SO<sub>3</sub> in 100 parts of weak solution.

*Approximate Calculation of Volume of Burner Gas at 32°F. and 29.92 in. (0°C. and 760 mm.).*—1 cu. ft. of SO<sub>2</sub> weighs 0.1787 pound av. (1 liter weighs 2.86336 grams), and contains 0.1787 ÷ 2 = 0.08935 lb. S. Therefore, 1 lb.

sulphur burned in 24 hours produces 11·191942 cu. ft. of  $\text{SO}_2$ , or 0·0077722 cu. ft. per minute: Therefore, neglecting  $\text{SO}_3$  formed

$$\left( \frac{0\cdot77722 \times \text{actual sulphur burned in 24 hours}}{\text{average per cent. of } \text{SO}_2 \text{ in burner gas produced}} \right) =$$

cubic feet of burner gas per minute, or for 10,000 lb. of sulphur burned in 24 hours  $(7\cdot7722 \div 7\cdot5) = 1,036\cdot3$  cu. ft. per minute of burner gas containing %  $\text{SO}_2$ .

*To Correct for Higher Temperatures at Normal Pressure.*—Co-efficient of expansion of air =  $0\cdot003667 = \frac{1}{271}$  and that of ordinary burner gas may be taken slightly in excess of that of air (say  $\frac{1}{270}$  to  $\frac{1}{271}$ ) at  $0^\circ\text{C}$ . and 760 mm. The volume at  $t^\circ\text{C}$ . is  $V + \frac{V \times t^\circ\text{C.}}{271}$  or for 10,000 lb. S in 24 hours 7·5%  $\text{SO}_2$

burner gas at 760 mm. and  $100^\circ\text{C}$ . (V as above = 1,036·3 cu. ft.)  
 $36\cdot3 + \frac{1,036\cdot3 \times 100}{271} = 1,418\cdot7$  cu. ft.

HYDRATES OF  $\text{SO}_3$ .

SULPHURIC ACID AND ITS MANUFACTURE BY THE CONTACT PROCESS.<sup>1</sup>

BY R. KNEITSCH.

It is hardly necessary to call special attention to the fact that the manufacture of sulphuric acid is a matter of the greatest industrial interest; for it is rightly considered as the basis not only of inorganic chemical industry, but also of the later years of the manufacture of organic dyes. In addition it is used in manifold industries. This is the case particularly in the manufacture of azo-dyes, and most recently in the manufacture of synthetic indigo.

When a complete revolution takes place in an industry of such importance, a presentation of these discoveries and proved principles which have made this revolution possible may be of interest. Briefly summarized the chief results obtained by the Badische Anilin & Soda Fabrik are as follows: The chemical reaction representing the production of sulphuric acid is an exceedingly simple one, and apparently chemistry plays only a subordinate part in it. This simple process is a very interesting and important example of a gas reaction which takes place only at high temperatures. The reaction between sulphur dioxide and oxygen, although it is exothermic, takes place only very slowly and for this reason has always been the endeavor of industrial chemists to accelerate it by the use of catalytic substances. The old chamber process itself is based upon the use of a catalytically acting substance, as nitric acid or the lower oxides of nitrogen.

There are also a number of solid contact substances which, however, act only at a higher temperature; but because they are solids, there is no loss of contact

<sup>1</sup> A lecture delivered before the German Chemical Society, Oct. 19, 1901. Translated by O. H. Ruhoff.

material. Above all they exercise their catalytic action in the complete absence of water, producing not dilute  $\text{H}_2\text{SO}_4$ , as in the chamber process, but sulphuric anhydride itself.

### I. HISTORICAL.

The historical development of the contact process may be divided into four periods, the first of which is opened in 1831 by the discovery of the catalytic action of platinum in the sulphuric acid process. The second period may be dated from the discovery by Mohler and Mahla in 1852 of the catalytic action of a number of substances and the clearing up of the mechanism of the reaction in the case of several catalysts. The third period was brought to life by Winkler, and is characterized by the use of certain particular mixtures of gases for the production of sulphuric oxide, which according to views held at that time, were particularly compounded for the quantitative production of anhydride. In the fourth period, finally, burner gases were again made use of.

The practical results to which these efforts tended, differed from each other in that the earlier ones, as also those of the fourth period, had as their object the supplanting of its chamber process by means of catalytic substances, while the workers of the third period, after the great number of failures of their predecessors, confined themselves to the production of fuming sulphuric acid which was at that time still very high in price.

The discoverer of the catalytic action of platinum in general was Humphry Davy,<sup>2</sup> who announced in January, 1817, that heated platinum wire, when brought into a mixture of oxygen or air with hydrogen carbon monoxide, ethylene, or cyanogen, etc., became heated to redness and that then the mixture burns sometimes slowly, often, however, rapidly. Edmund Davy discovered in 1820 that finely divided platinum obtained by precipitating a solution of platinum with hydrogen sulphide, treating the precipitate with nitric acid, evaporating the solution and boiling the residue with alcohol, glowed in the air, the alcohol being consumed. Dobereiner found in 1822 that the residue obtained by heating ammonium platino-chloride when moistened with alcohol shows the same phenomenon in the air, and in 1823 that in the presence of air finely divided platinum ignites a current of hydrogen directed against it. Upon this fact Dobereiner based his famous lighting machine in 1824. The honor of having applied this catalytic action to the production of sulphur trioxide belongs, as before mentioned, to the acetic acid manufacturer, Peregrine Phillips, Jr., of Bristol, who took out an English patent<sup>3</sup> on his invention in the year 1831.

Soon after, in the year 1832, two eminent German scientists, Dobereiner and Magnus<sup>4</sup> confirmed the discovery of Phillips. After Phillips' discovery had remained idle for 17 years, the problem of the manufacture of sulphuric acid

<sup>2</sup> Kopp, *Geschichte der Chemie*, Vol. 3-4, p. 226.

<sup>3</sup> English Patent No. 6,006, 1831.

<sup>4</sup> Mangus confirms, in *Poggendorfs Annalen*, 24, p. 610, Phillips' assertion that sulphurous acid and oxygen, or air (the latter only more slowly), heated with platinum or, better, spongy platinum, may be condensed to sulphuric acid, and Dobereiner says in the same journal at the end of a discussion on making of oxygen ethers by means of platinum black: "I have succeeded in condensing a mixture of two volumes of sulphurous acid by means of hygroscopically moist platinum black." Even though Dobereiner does not mention Phillips' name it may be assumed with certainty that he, as well as Magnus, knew of Phillips' discovery and the work of both of them was only intended to prove Phillips' assertions.

without lead chambers was claimed as solved by the Belgian chemist Schneider,<sup>5</sup> who, as he stated, believed he had found in a specially prepared pumice stone a catalytic substance of high activity. This alleged discovery, though given to the world with much ado,<sup>6</sup> never gave evidence of any success. The sanguine hopes of that period are evidenced by a portion of a letter which Clement Desorme wrote to Schneider in the year 1835, years after Phillips' discovery. It reads literally as follows: "I am convinced that in at most 10 years it will be possible to manufacture sulphuric acid on a large scale, out of its constituents, without lead chambers, nitric acid, or salts; do not lose courage, and direct your efforts toward this important end."

From this it is evident that the great object was plainly marked out even in the year 1835.

Richard Lovering was just as over-sanguine as Schneider in the description of his discovery, for he too claimed to have discovered a process for the production of sulphuric acid without the use of lead chambers. Again pumice stone was said to be exerting its wonderful power, and prepared by being boiled in concentrated sulphuric acid, then brought into ammoniacal water, dried, and thereupon treated with about 1% of  $\text{MnO}_2$ . Then it was to be again treated in a retort to 600°F. and allowed to cool without access of air. Here, for the first time, is mentioned a different contact substance, which, like platinum, occurs in different degrees of oxidation, viz.: manganese compounds. But here too, a complete failure seems to have destroyed great hopes, as in Schneider's case. According to Dengler, Lamun's patent was even a plagiarism on Schneider's work.

The English patent of 1846, by Jullian,<sup>7</sup> deserves particular mention, because here the use of platinized asbestos is mentioned for the first time. Jullian intended to use this catalytic substance, which later became so important, among other things for the production of sulphuric acid. As forerunners of the second period there appears the beforementioned work of Lamun as also the experiments of M. C. Blondeau<sup>8</sup> (1849). The latter passed a mixture of sulphur dioxide steam and air through a glowing porcelain tube filled with clayey sand containing iron, and obtained sulphuric acid.

<sup>5</sup> Schneider exhibited before a Belgian committee a model apparatus in which he made sulphuric acid for a whole day by burning sulphur. The committee came to the following characteristic conclusions, based on Schneider's claims and experiments:

"(1) That according to Schneider's method, sulphuric acid can be made without the use of nitric acid or nitrates. (2) That the yield of acid approaches the maximum hitherto reached in sulphuric acid plants. (3) That the committee is not acquainted with the method by which the property of combining sulphurous acid with the oxygen of the air is imparted to pumice, so that it must confine itself to mentioning the inventor's claim that his manner of preparing the pumice stone involves but a slight expense." What the secret manner of preparing the pumice stone was, therefore, was not made public, but it is very probable that Schneider wanted to profit by Phillips' discovery without mentioning it, but grossly deceived himself regarding the discovery. In the year 1848, he says, for instance, regarding his alleged discovery: "Of late the most eminent chemists, Gay-Lussac, Clement, Desormes, Dumas, Payen, Bussy, Chevallier, Peligot and others have been working on this discovery. But there is still lacking an apparatus enabling us to do without the lead chambers in the manufacture of this acid. I believe that I have solved this problem in its practical as well as its scientific aspect."

<sup>6</sup> Schneider closes his experiments in the year 1848 with the words: "I believe that I have neglected nothing in achieving a result which is an important advance in the manufacture of sulphuric acid. My chief purpose was to construct an apparatus which can take the place of the lead chambers and the platinum stills. I have been completely successful in this."

<sup>7</sup> English Patent No. 11,425, 1846.

<sup>8</sup> *Comptes Rendus*, 29, 406, 1849. Blondeau's work was based upon an observation of Boussignault's, who had noticed that sulphuric acid occurred in rivers in whose vicinity the gases of burning iron sulphide deposits had been converted into sulphuric acid by the heat of the combustion under the influence of clayey sand and slate.

Then came Mohler and Mahla's discovery in 1852 that copper, iron and chromium oxides gave evidence of catalytic properties similar to spongy platinum and sheet platinum with a mixture of sulphurous acid and oxygen, and that mixtures of copper oxide and chrome oxide were particularly active. These investigators, too, gave even then a correct explanation of catalytic action, for they found that copper oxide and ferric oxide, heated without blast excess of air are reduced to cuprous acid and ferrous acid, with formation of sulphuric acid. As soon as the reduction is complete the formation of sulphuric acid stops. Chromic acid, however, remains entirely unchanged when heated with sulphuric acid without presence of air, and no trace of sulphuric acid is found. Metallic copper in the spongy form, or mercury, brought into a mixture of two volumes of sulphurous acid and one volume of oxygen, have no action on each other. If, however, heat is applied, then, when copper is used there is first formed copper oxide and only then sulphuric acid. The two investigators further pointed out that the presence of moisture in the gases is not necessary for the formation of sulphuric acid. These important observations are the foundation of the later investigations of Lunge in the catalytic action of burnt pyrites, as also the very recently worked out process for the production of sulphuric acid by means of burnt pyrites, of the Verein Chemischer Fabriken.<sup>9</sup>

In the year 1852 Plattner and Reich likewise worked with the use of heated quartz, but unsuccessfully. It is very interesting to note that even at this time Robbe proposed ferric oxide or powdered pyrites cinders as contact substances. Pirie recommended, besides heated quartz, pumice stone saturated with a solution of platinum as a substitute for metallic platinum. Thornthwaite<sup>10</sup> (1854) comes in for mention at this place. Among other things he again took up Jullian's idea of using platinized asbestos, manganese dioxide, first mentioned as contact mass by Lamung, and further had Mohler and Mahla's observations protected for himself by an English patent. Into this period there belongs further the work of Alfred Truemann.<sup>11</sup> He impregnated clay with platonic-chloride, and formed from this a red heat metallic platinum.<sup>12</sup>

Hundt,<sup>13</sup> in 1854, allowed burner gases to pass through a canal which was heated up by the heat of the gases themselves and which was lined with pebbles so as to convert as large a portion as possible of the sulphurous acid into sulphuric acid, and then worked up the burner gases further.<sup>14</sup>

In the year 1855 Schmersahl and Bank<sup>15</sup> prepared sulphuric acid by passing sulphur dioxide, air and steam over heated contact substances, absorbing the sulphuric acid thus formed, and continuing this process until all the sulphur dioxide had been converted into sulphuric acid.

Henry Deacon<sup>16</sup> took out patents in the year 1871 aside from those on his

<sup>9</sup> German Patents Nos. 107,995 and 108,446. <sup>10</sup> English Patent No. 188, 1854. <sup>11</sup> English Patent No. 998, 1854.

<sup>12</sup> Trueman's patent treats of the use of platinum or ferric oxide with pumice stone or other porous materials, for the manufacture of sulphuric acid from burner gases. He describes also the use of porous substances which have been saturated with the sulphates of iron, copper, chromium and manganese, and then heated to redness, in order to form the active oxides by driving off the sulphuric acid.

<sup>13</sup> English Patent, Feb. 16, 1854.

<sup>14</sup> Hundt believed also that the burner gases could be converted into sulphuric acid in sprayed towers alone, without the use of chambers.

<sup>15</sup> English Patent No. 188, 1855.

<sup>16</sup> English Patents Nos. 758 and 1,082, 1871.

celebrated chlorine process, in which the production of sulphuric acid by means of his contact substances, especially copper sulphate, is described.<sup>17</sup>

This closes the second period of the historical development, which, like the first, is characterized by having made its purpose the attainment of the—I should like to say “great”—end, of supplanting the chamber process by the contact process. These efforts, however, gave no evidence of practical success, and it was not even possible to produce fuming sulphuric acid cheaply enough to compete with Stark’s product obtained by the distillation of slate containing iron sulphate. The turning point in the manufacture of sulphuric acid was made by the work of Clemens Winkler who, from experimental investigations on the formation of sulphuric acid from sulphur dioxide and oxygen, came to the conclusion that only a stoichiometrical mixture of 2 volumes of  $\text{SO}_2$  and 1 of  $\text{O}$  was suitable for a conversion of these into  $\text{SO}_3$  as complete as possible, and that all other gases, even oxygen, exercised a harmful influence on the progress of the reaction. This stoichiometrical mixture Winkler produced in a very simple manner by decomposing ordinary hydrated sulphuric acid by means of heat, into water, sulphurous acid and oxygen, and removing the water. In this way he obtained by the subsequent concentration of the gases, sulphuric anhydride or fuming sulphuric acid. This work, which became celebrated, was published in *Dingler’s Journal* in 1875. The assertion based by Winkler upon his experiments read as follows: “According to these experiments, of 100 parts by weight of sulphurous acid used there are converted into sulphuric acid under various circumstances: (a) of a mixture of pure sulphurous acid and pure oxygen, 73.3 parts by weight; (b) of a mixture of pure sulphurous acid and air, 47.4 parts by weight; (c) of a gas containing 4 to 5% by volume of sulphurous acid obtained by burning sulphur in a current of air, 11.5 parts by weight.

“It is evident from this that the action of platinized asbestos and doubtless of other contact substances is decreased in proportion as the dilution of the sulphurous acid by other indifferent gases becomes greater. Of course oxygen and sulphurous acid themselves remain inactive and so act as diluents in so far as they are not present together in the stoichiometrical proportions necessary for the formation of sulphuric acid, and one or the other is present in excess. In the abovementioned experiments this condition was unavoidable, and it may be for this reason that even when pure oxygen was used, only about 75% of the sulphurous acid was converted into sulphuric acid.

“It is a well-known fact that ordinary English sulphuric acid is broken up at a bright red heat into sulphurous acid, oxygen and water vapor. Of these three decomposition products the water vapor can be completely condensed, and there then remains a gaseous mixture of oxygen and sulphurous acid in exactly the proportions necessary for making sulphur trioxide. In this way it was possible to prevent the harmful admixture of any indifferent gases, and it was now only necessary to recombine the dried decomposition products, by contact action. There would thus be formed sulphuric acid, and the whole process

<sup>17</sup> Deacon noticed the fact that the reaction takes place better when air or oxygen are used in excess, but mentions that in that case larger quantities of gas have to be heated and moved.

amounts then to an indirect transformation of hydrated sulphuric acid to anhydrous acid."

This view of the most suitable conditions for the contact process for sulphuric acid appeared to be very reasonable, at that time, and well suited to explain all the failures of Phillips' reaction when applied to the utilization of the burner gases. Winkler's work caused a great stir at that time and influenced further work on the contact process for a long time after that. At about the same time the same process was discovered also in Messel's<sup>18</sup> works and protected by patents. Winkler published a new method for making contact substances, *viz.*: by utilizing the reducing action of formalin.<sup>19</sup>

This daring advance of Winkler's at once called into life the technical synthetic production of fuming sulphuric acid which up to that time had been attempted in vain, for a number of manufacturers,—among the first of whom was the Badische Anilin & Soda Fabrik,—took up the new process, with his work as a basis and Stark's monopoly in Bohemia was broken. For this reason the whole industrial world has occasion to be thankful to Winkler for the stimulus given by him to technical work. Further work in this field was now ruled by Winkler's influence, for example, Hänisch & Schröder's<sup>20</sup> patent, taken out 11 years later; they replaced pure oxygen by air but still used pure sulphur dioxide and as a correction for the diluting influence of the nitrogen had the reaction take place under pressure, in order, as the patent says, to bring the molecules of the gases closer together. This process, too, was tried in the Badische Anilin & Soda Fabrik. Messel<sup>21</sup> and Lunge (Ellice Clark<sup>22</sup>) proposed a method of obtaining the stoichiometrical mixture and excluding the nitrogen of the air, *viz.*: by roasting pyrites with oxygen. None of these processes, however, was capable of competing with the chamber process, and therefore had to be confined to making the fuming sulphuric acid.

Still further attempts to solve this problem have not been lacking but practically nothing has become public about such work. Winkler himself published nothing about his work in this direction, nor any results he may have obtained that conflicted with his publication, so that it was only a year ago that it became known by Lunge, and Winkler's significant lecture in Hanover on the development of sulphuric acid manufacture, that at his instigation however burner gases had been used at the Muldener furnace and two-thirds and at most three-quarters of the sulphur dioxide obtained in them had been converted into sulphuric acid.

From a patent of Rath's, too,<sup>23</sup> which deals with the utilization of burner gases, evenly mixed with fire gas, nothing of importance can be gathered. The patent gives chiefly a description of how the gases are to be freed from moisture and unconsumed organic admixtures, while no particulars are given about the contact process itself other than that the gases are to be led through contact cylinders heated to redness. Nothing was ever heard of any practical success of the process.

## II. PURIFICATION.

The problem of transforming burner gases completely into sulphuric acid by the contact action remained for solution, but considering everything that was known about it at that time, it was regarded as hopeless. When I approached the problem in the works of the Badische Anilin & Soda Fabrik, it was chiefly theoretical considerations which made the possibility of accomplishing the great purpose seem not altogether hopeless, as it is well known the gases leaving the sulphuric acid chambers still contain 6% of oxygen. If no change was made in roasting, there would have to be this same excess of oxygen in every contact process working with burner gases, and it was not comprehensible why in spite of such an excess of oxygen the reaction should not take place quantitatively. This question was investigated with purposely highly diluted gases made by mixing pure sulphur dioxide gas with air, and it could be proved that under certain conditions a complete cessation of the reaction occurred only very close to a quantitative conversion. Strange to say it was found that the greatest dilution with air had practically no influence on the transformation into sulphur dioxide of the sulphur dioxide gas that was present. It even seemed that the conversion was improved in proportion with the dilution; the relation between oxygen and sulphur dioxide gas in the mixture being changed in favor of the oxygen.

It proved from this fact that the views held up to this time that diluting gases acted unfavorably on the progress of the contact process required a critical investigation. Experiments were now tried with conditions as they occur in practice, that is, burner gases. For this purpose burner gas was led directly to the laboratory from the pyrites burners by means of a long lead pipe, the latter acting as a long dust canal, and freeing the gas as much as possible from flue-*gas* and other mechanical impurities. Besides this the gas was drawn through several wash bottles containing sulphuric acid before it entered the tube containing the contact mass. The result was gratifying in no slight degree, for almost as favorable results were obtained in this way as before with an artificial gas mixture.

A decrease in the contact action could not be noticed though the action was continued for several days with the same contact mass, so that it seems quite justifiable to hope that in this very practical manner sulphuric acid could be produced almost quantitatively directly from burner gases. The experiments were therefore tried on a large scale. It was now seen very soon that the activity of the contact mass did not remain constant after having been used for some time and finally ceased entirely. There was no change in this state of affairs when the burner gases were not only cooled in long canals and repeatedly washed with sulphuric acid—exactly as in the laboratory experiments—but were also passed through dry coke and asbestos filters, so that they could be regarded as clean as was technically possible. The experiments on a large scale had to be considered failures; then, though confidence in success had been badly shaken by these unexpected failures, further laboratory experiments were made in order to determine the cause of the slow but none the less sure deterioration of the contact mass.

In these experiments the surprising discovery was made that there are substances which even in exceedingly minute quantities, can diminish the catalytic action of the platinum to an extraordinary extent. Among the first of these substances belongs arsenic, quicksilver, and phosphorus,<sup>24</sup> while antimony, bismuth, lead, iron, zinc, and other substances which would have to be taken into consideration in roasting, are harmful only in so far as they naturally cover and clog the contact mass when carried over into it. The harmful action of arsenic alone, for example, was found to be so great that even quantities amounting to 1 to 2% of the platinum contained in the contact mass sufficed to make it entirely inactive. By these investigations it had, then, been irrefutably determined that there are bodies which are actually capable of exerting a specific, one might almost say, poisonous action on the contact process. The question was therefore, whether, in spite of the method of purification described above, there were still bodies of the character contained in the burner gases used. It could be determined, in fact, that the white mist of sulphuric acid in them which could not be precipitated, contained chiefly arsenic.

Though the reason for our failures appeared to have been revealed by the recognition of this fact, still no remedy for the evil was known. For at that time the complete deposition of the white mist, the so-called "Hüttenrauche" (arsenical fume), was considered technically impossible according to the most eminent experts.<sup>25</sup> The prospects for ultimate success after such long and laborious efforts now became very doubtful. But now that the harmful influence had been discovered, the new problem to be solved was taken up with renewed energy; this was, to free the burner gas of all impurities completely so that finally there would remain only a mixture of absolutely pure gases, viz.: sulphurous acid, oxygen and nitrogen.

With an enormous expenditure of time, trouble, money and patience, experiment was followed by experiment in order to accomplish this great purpose, and it may be said without exaggeration that it was one of the most difficult problems in the progress of the industry to show the well-known revolution in the sulphuric acid industry. It is impossible in this short time to go into the details of the experiments, which required several years of the severest effort after the process was being tried on a large scale, before a positively certain purification of the burner gases could be regarded as having been accomplished. The difficulty of this problem lay chiefly in the fact that there had to be carried on a wearing struggle with, one might say, an invisible foe, and that every misstep avenged itself by influencing for some time the output of the whole work. The result<sup>26</sup> of this is that it has become quite possible to rid the burner gas

<sup>24</sup> A subsequent and more searching investigation of the harmful action of phosphorus showed that this was only the result of the arsenic it contained.

<sup>25</sup> Extract from *Schnabel's Hüttenkunde*, 1890, p. 500: "Contrivances for catching flue-dust and for condensing metallic vapors in furnace gases (Hüttenrauch), are based upon cooling, filtration, washing, contact with surfaces, diminution of velocity and change of direction of the current of gas. Electricity of high tension has also been used as an experiment. Neither the first-mentioned methods, separately nor a combination of them in the most various ways have until now been found sufficient for completely freeing "Hüttenrauche" from the substances mentioned. A large field for inventive genius is still open in this field."

<sup>26</sup> German Patent No. 113,933, July 22, 1906.

completely of all its impurities, by subjecting it, after suitable treatment and cooling, to a systematically continued intimate contact with water or sulphuric acid. This has to be continued until an optical and chemical examination demonstrates the complete absence of all harmful admixtures. The manner in which the intimate contact with purifying liquids is obtained is a matter of indifference so far as the final result is concerned. For example, extensive washing and moist filtration, alone or in combination, were found to be equally effective. I should like to mention in particular only a few of the difficulties which came up in the purification of the gases on a large scale. To obtain good results it had been found best to cool the gases slowly. For it is an exceedingly remarkable and as yet not sufficiently explained phenomenon, that the sulphuric acid mist of the burner gas is deposited with much greater difficulty when the latter is cooled rapidly than when cooled slowly.

For this purpose there was necessary a long iron flue which could be cooled by the air. Nothing was known at that time of any harmful influence that such a flue might exert on the contact process, for the sulphuric acid contained in burner gases when dry pyrites are used, has a strength of over 90%  $\text{H}_2\text{SO}_4$ , so that if the iron were attacked it was to be expected that it would be only with evolution of sulphur dioxide, which in itself could not be harmful to the process. In spite of the fact that the gases were now completely free from mechanical impurities, so that the optical test which at that time was still regarded as sufficient, did not give evidence of even the slightest trace of any impurity, the gases were even filtered through masses of moist filtering material, so arranged as apparently to secure perfect purification, yet it was seen that the contact mass lost its activity very slowly (only after weeks and months) but with unflinching certainty. After long and difficult lapses and after the presence of arsenic, in spite of its apparently complete removal by the above described process of purification had been confirmed with certainty by examination of the inactive platinized asbestos, it was conjectured that the cause for all these disturbances might be traced to the reaction products, the sulphuric acid condensing in small quantities in the iron cooling flues, and it became more and more certain that arsenical gas, probably arsine ( $\text{AsH}_3$ ) must have been formed here. Such changes were made as were necessary to prevent the condensing sulphuric acid from coming in contact with the iron cooling flue, and from this time the activity of the contact furnaces remained unchanged; some hydrogen must have been evolved by the action of concentrated sulphuric acid on iron, contrary to the views held up to that time, for it is only thus that arsine ( $\text{AsH}_3$ ) can be formed.

This ended probably the most obstinate struggle that was fought in the introduction of the new sulphuric acid process, although this struggle was not the last. In carrying out the process on a still larger scale, new disturbances occurred in the purification of the gases, whose causes were almost as mysterious and impossible to foresee as the one above mentioned. When the pyrites burners were run to their full capacity, there resulted misty formations which mocked all efforts to precipitate them. The explanation for their existence was finally found after a long search in very slight quantities of mist composed of uncon-

sumed sulphur. This mist, like quickly cooled sulphuric acid mist, could be deposited only with the greatest difficulty. But how could sulphur act harmfully, when it would only burn to sulphurous acid in the contact apparatus? The explanation is that the sulphur mist also was found to contain arsenic, and therefore had to be removed.

A radical means for the purpose was finally found in the thorough mixing of the still hot burner gas, so as to insure the combustion of even the last traces of sulphur. This mixing is most suitably accomplished by means of a jet of steam, the use of which is attended with the important advantages that the strong sulphuric acid present in the gas is diluted, and does not condense in the preliminary iron coolers, therefore not attacking them with formation of arsine nor, as a result of its low concentration does it destroy the main coolers of lead, when it condenses. Besides this the steam prevents the formation of hard crusts of flue-dust in the canals and coolers, which otherwise easily causes them to become obstructed.

The problem of regenerating a contact mass which has become inactive is dealt with by two patents<sup>27</sup> of the "Actien Gesellschaft für Zink Industrie vorm: Grillo & Schroeder. Their mode of procedure is based on the assumption that it is impossible in practice to remove all impurities from the gases. One of their patents therefore proposes the use of soluble salts as a carrier for the platinum, so that the ineffective platinum may be regenerated, while the other consists of removing the inactive contact mass by means of chlorine.

### III. REGENERATING COOLING.

We come now to another principle of great importance in the contact process, viz.: the rational removal of the harmful excess of the heat of reaction. As is known, the chemical process taking place in the contact process, is exothermic and may be expressed as follows:—

But little attention had hitherto been paid, in the technology of fuming sulphuric acid, to this great evolution of heat. It is true that in Lunge's *Handbuch der Soda Industrie* reference is made to a process which is said to consist of heating a mixture of pure sulphur dioxide and air only to the temperature necessary for the contact process and then to allow it to pass into a contact apparatus which is not to be further heated, but only protected as much as possible from cooling, and which similarly to a Deacon chlorine apparatus was filled with platinized spheres of clay. But in this apparatus there was used a highly contracted mixture of gas, containing about 25% SO<sub>2</sub> by volume, and no conclusions could be drawn from it with regard to conditions that would exist when burner gases from 3 to 4 times more dilute were used. On the contrary it was generally considered necessary in the use of ordinary gas mixtures, not only to protect the contact vessels against radiation but to heat them directly to redness.

Accordingly, the contact apparatus first constructed by us was provided with

<sup>27</sup> German Patents Nos. 115,333 and 102,244.

heating arrangements suitable for this purpose. In order to economize in costly platinized asbestos, vertical contact tubes of not too great width were used, since it was found that in such tubes the platinum asbestos could be uniformly distributed with greater certainty than in other horizontal tubes or vessels. Thus the contact furnace consisted of a series of narrow iron tubes, the lower halves of which were filled with contact mass, as is shown in the accompanying drawing taken from our patent (Fig. 1A). When this furnace was set into operation at the customary low red heat, the exceedingly surprising observation was made that not only the yields rose, but that also the volume of the current of gas could also be very comfortably increased if in place of the hot fire gases from the lower heating arrangement, cold air was introduced between the pipes and thereby the

FIG. 1A.

FIG. 1B.

CONTACT APPARATUS OF THE BADISCHE ANILIN UND SODA FABRIK.

temperature of the furnace materially lowered. By this experiment the road was opened to a rational operation of the contact furnaces,<sup>28</sup> just the opposite of the former mode of procedure. The furnaces had to be cooled in an adjustable manner if there was to be a maximum conversion and capacity. Such a furnace was operated by first heating up the cold furnace with both heaters, *h* and *h'*. As soon as the furnace had been set in operation the lower heater *h* was extinguished and cold air led by the contact mass, so that on the one hand the mass was cooled, and on the other hand the mass affected by the rising heated current of air and heating of the incoming cold gases which had to be completed by the heater *h'*. As could be seen with the eye, only the upper layers of the contact mass now became heated to dull redness, and by the passage of the

<sup>28</sup> German Patent No. 113,932, June 3, 1896.

gases there was maintained a degree of heat best suited for the completion of the reaction. This simple mode of operation and type of furnace which I have described stood the test of years; further the temperature may be observed continuously even without pyrometers, by the direct observation of the series of tubes.

Further investigation showed that the quantity of heat which could be extracted without injury from the contact process was so great that it seemed possible to use the burner gases themselves as cooling gases and thus utilize the excess heat of reaction directly for preheating the cold burner gases. In this way originated the various modifications of our apparatus described in our German patent, one of which, for example, is shown in Fig. 1B.

The manner of utilizing the heat of reaction is described by a patent of the "Höchstes Farbwerke,"<sup>29</sup> according to which the heat of the gases after they have left the contact vessel is made use of. If we consider the effects of the cooling of the gases more closely we find that by it chiefly four important results are accomplished: (1) An overheating of the apparatus is prevented and such a temperature maintained as assures securing the theoretically possible highest yields, that is, 96 to 98%. (2) The iron apparatus is protected against premature destruction by the lower temperature at which the reaction takes place. (3) The contact mass is kept from becoming overheated and retains an undiminished degree of activity for years, and (4) The absolute capacity of the contact mass and thus also of the apparatus, is quite considerably increased, because fresh quantities of gas can continually be passed through the contact mass without overheating it, and because the contact mass itself is brought to a temperature most favorable for the greatest capacity. Should the furnace become overheated it is now no longer necessary, as formerly, to diminish the quantity of the gas to be converted, but its cooling action is regulated by varying its quantity, or its temperature as it enters the cooling spaces, or by a suitable change of the point at which it enters.

Another encouraging characteristic of the new process is that the reaction takes place without the application of pressure. You will remember that according to the views formerly held, the influence of inert gases was to hinder the reaction so that it was believed that this harmful influence had to be counteracted by using highly compressed gases. But, either there is no such influence or it amounts to practically nothing. There is not the least difficulty in obtaining under the right conditions, even without additional pressure, a quantitative conversion of  $\text{SO}_2$  to  $\text{SO}_3$ . This fact is of great importance in practice; for when it comes to competing with the chamber process, all large expenditures must be avoided. To carry on the process rationally it is, on the other hand, necessary that the gas should be compelled to pass through the contact mass itself and come into the most intimate contact with it. But with such loose material as platinized asbestos, this necessitated a firm, close packing, which again resulted in a great resistance to the passage of the gases.

The object to be accomplished therefore was to reduce the resistance in the contact mass to a minimum without however leaving any other passageway open for the gas except through the mass, and still not to make it impossible

<sup>29</sup> German Patent No. 105,876.

to cool the contact tube. This was accomplished by a very simple apparatus<sup>30</sup> which is explained by Fig. 1A. The contact mass is distributed on perforated plates which are strung upon a central round iron rod, and the pressure of the separate layers on each other by short pieces of pipe or short pegs inserted between them, so that there is only the resistance of the loose contact mass opposing the current of gas, which, however, is exceedingly slight, so that only a small mechanical force is necessary to overcome it.

This manner of filling also has the great advantage that the tubes can be filled so as to produce in all of them an equal pressure which can easily be tested in any one, so that the whole apparatus, even if consisting of a great number of such contact tubes is absolutely certain of securing an equal distribution of the gas, thus doing the best possible work.

#### IV. ABSORPTION.

We come now to the question of the best method for absorbing the sulphur trioxide in the gases.

As is well known, sulphur trioxide has a much greater affinity for water than for concentrated sulphuric acid, which fact is numerically expressed by the heats of absorption.<sup>31</sup>

The most natural method of procedure would be, therefore, to set up in a row a number of absorption vessels in which the absorbing sulphuric acid increases in concentration in the direction of the gas current so that water or chamber acid or other dilute sulphuric acid would follow into the last vessel, and fuming sulphuric acid or acid of such strength as may be required, flow from the first.

Such a method, contrary to all appearances, does not result in the highest absorption capacity; it is, on the other hand extremely difficult to absorb sulphur trioxide completely in water or dilute sulphuric acid, for considerable quantities of white mist which will condense only with great difficulty, always leave the vessel causing considerable losses. It has been found however that sulphuric acid of a very limited range of strength, viz.: from 97 to 98%  $\text{H}_2\text{SO}_4$ , will absorb sulphur trioxide instantly and completely.

As is shown from the compilation of the properties of sulphuric acid in the curves, grouped together for purposes of comparison, there takes place at the abovementioned, I should like to say, critical concentration point, a whole series of changes in the properties of sulphuric acid. In the first place, at this concentration the boiling-point curve makes a remarkably sharp turn, which is characterized by the fact that at all points to its left, water or dilute sulphuric acid distil off until a strength of about 98.3%  $\text{H}_2\text{SO}_4$  is reached, at which the acid then distils over from beginning to end at the same concentration and at the same constant boiling point of about 330°C. like a simple substance. From all strengths to the right of this point, on the other hand sulphur trioxide is distilled off until again the same concentration of 98.3% is reached.

The vapor pressure, measured at 100°C. in a vacuum, shows a minimum at

<sup>30</sup> German Patent No. 119,069, July 23, 1896.

<sup>31</sup> When 1 kg. sulphuric anhydride is mixed with much water, then are liberated about 500 calories while by the solution of 1 kg. sulphuric anhydride in much sulphuric acid of 66°B. only about 300 calories are developed.

this point, or more correctly, can scarcely be detected by ordinary means as is seen by the curve.

The specific gravity of hydrated sulphuric acid is highest at this point. It is here also that there is the greatest contraction of sulphuric acid, the electrical resistance suddenly begins to rise at this point and attains a maximum close to monohydrate with remarkable rapidity. Closely connected with this is the fact that the rapidity with which iron is attacked at this concentration reaches a minimum which of course is of the greatest importance when the durability of vessels is considered.

The absorbing power of this strength of acid is so enormous that it is possible completely to deprive a rapid current of gas of its sulphur trioxide in a single vessel, provided of course that the concentration of the acid is always kept constant at 97 to 99%  $\text{H}_2\text{SO}_4$  by a continual addition of water and a continual removal of the excess of sulphuric acid that is formed.<sup>32</sup>

For making fuming sulphuric acid one or more absorption vessels must be inserted before the one kept at 97 to 99%  $\text{H}_2\text{SO}_4$ . Here, again, other very remarkable phenomena may be observed. While cast-iron vessels are well suited for use with watery sulphuric acid, resisting its action very well, they cannot be used with fuming acid of any kind, for while cast iron is attacked but little, what is much worse,—it explodes. This remarkable phenomenon is based upon the fact that oleum diffusing in the pores of the cast iron, begins the work of destruction there by being converted by the reducing action of the iron into sulphuric dioxide and hydrogen sulphide, and some times even generating carbon dioxide from the carbon of the iron, all of them gases whose critical temperatures are quite low, and as a result of this cause high tensions within the cast iron. If such a piece of iron is broken in fragments, sulphur dioxide and hydrogen sulphide are distinctly recognizable by the odor, and their evolution of gas can be perceived by immersing them in a suitable liquid. This portion of a valve shows very plainly the beginning of this action.

In contrast to cast iron, wrought iron is comparatively rapidly attacked by weak fuming acids up to oleum containing about 27% free  $\text{SO}_3$ . This action evidently has its scientific explanation in the increase of the electrical conductivity of these corrosive strengths of oleum.

A glance at the curve of the conductivity of the various concentrated acids (Fig. 2) shows that after reaching a minimum appearing as a sharp point at monohydrate, oleum again became strongly conducting, until a maximum is reached at about 10 to 15% oleum, when it again falls just as rapidly to infinitely small values. Its corrosive effect upon wrought iron (and also upon zinc) undergoes changes very similar to those in the electrical conductivity, as may be seen from the figure.

In oleum with about 27% free  $\text{SO}_3$ , wrought iron becomes practically entirely passive, and wrought iron vessels can be used for many years for manufacturing oleum of high sulphur trioxide content without being perceptibly attacked.

On these observations we based a method for the production of almost absolutely iron free sulphuric acid.<sup>33</sup>

<sup>32</sup> B. A. & S. F. Patent Ann. B. No. 28,724.

<sup>33</sup> B. A. & S. F. Patent Ann. No. 28,200.

Sulphuric acid has a number of other properties of general as well as practical interest, some of which are presented in the accompanying curve diagram.

Perfectly pure sulphuric anhydride is, as is perfectly well known through Rudolph Weber's researches, liquid at the ordinary temperature, melting at  $17.7^{\circ}\text{C}$ .<sup>24</sup>

Its melting point is raised by the addition of small quantities of water and reaches a maximum of about  $27^{\circ}$  at 85% free  $\text{SO}_3$ . These statements hold only for freshly prepared mixtures, because after standing, oleum polymerizes and then does not melt any more at all, but sublimes directly at higher temperatures, again reverting to the ordinary modification.

Continuing the dilution the melting point falls to from 0 to  $2^{\circ}\text{C}$ . and reaches a minimum at this point with oleum having 60 to 65% free sulphur trioxide and then rises again to a maximum of  $36^{\circ}$ , which unquestionably belongs to pyrosul-

FIG. 2.—CURVES OF PHYSICAL PROPERTIES OF ORDINARY AND FUMING SULPHURIC ACID.

phuric acid,  $\text{H}_2\text{SO}_4 + \text{SO}_3$ . This highest point is further of interest in that it corresponds very closely with the greatest density, the greatest viscosity, and a distinct angle in the curve of capillarity.

Further dilution brings us to the strengths of oleum which corrode iron, having a minimum melting point of  $12^{\circ}$ , and here the curves of electrical conductivity, corrosive effect, and melting point show similar forms. The curve then rises again and reaches a maximum of  $+10^{\circ}$  at monohydrate. Still further dilution results in a decided fall of the freezing point; a minimum of  $-35^{\circ}$  is reached at a concentration very familiar to us, the so-called acid 66°B. of commerce, the hydrate  $2\text{H}_2\text{SO}_4 + \text{H}_2\text{O}$ , and then the curve rises again to  $+8^{\circ}$  at the hydrate  $\text{H}_2\text{SO}_4 + \text{H}_2\text{O}$ , to fall to below  $-50^{\circ}$ , from which it rises only at 30% acid, and from 20% sulphuric acid it falls almost in a straight line to  $0^{\circ}$ . (Ac-

<sup>24</sup> R. Weber found the melting point to be  $14.8^{\circ}\text{C}$ ., but he did not have the thermometer in the liquid. If this is the case the sulphuric anhydride all melts at  $17.7^{\circ}\text{C}$ .

according to Thilo there seems to be another maximum at 57%  $\text{H}_2\text{SO}_4 + 4\text{H}_2\text{O}$ .)

It is noteworthy that every summit of the melting-point curve corresponds to a simple hydrate which solidifies constantly as a single substance, while the depressions of the curve represent mixtures of the neighboring hydrates combined in the form of crystals. If the crystals of the concentrations lying between the high points of the curves are examined they will be found to have a composition characteristic of concentrations at the summits of the curves. Upon this Lunge<sup>35</sup> based his well-known process for making monohydrate. Hydrates corresponding to the other summits could be technically produced in a similar manner, if it were still of interest to do this.

The curve of the specific heats too, has a noteworthy form, falling continuously to about 20% oleum, and then rising again to the high value of 0.77 at pure sulphuric anhydride.

The curve of the heats of solution of sulphurous acid and sulphuric acid on the other hand, is quite regular so that the formation of the various hydrates seems to have no practical effect in this.

The curve of viscosity is noteworthy in that water and sulphuric anhydride have almost the same viscosity. Its highest point lies at the greatest density of fuming sulphuric acid, with a second, lower turn at the hydrate  $\text{H}_2\text{SO}_4 + \text{H}_2\text{O}$ .

As is evident, sulphuric acid offers such a variety in its properties that it is specially suited for purposes of instruction.

In the melting point phenomena we have an excellent illustration for presenting the theory of eutectic combinations. It can be used to present very clearly, and at the same time so as to be of the greatest value practically, the interesting phenomena of electrical conductivity, their important relations to purely technical questions, such as the degree in which metals are attacked, the phenomena of heat of solution, of variable specific heat, of various contractions of volume, as also the difference in behavior toward metals of the iron and copper group.

On several of these properties there can be based analytical methods for the determination of sulphur trioxide without the use of balance, which may often be of value in practice where specific gravity is no guide.

#### V. THEORY OF THE CONTACT PROCESS.

I shall proceed now to a closer consideration of the contact process itself. For this purpose allow me to present to you the details of a few fundamental experiments.

First, considering the reaction as it takes place at various temperatures and with various quantities of gas, we see that a quantitative conversion of the sulphurous acid into sulphuric anhydride cannot be accomplished under technically possible conditions, when burner gas is used, which contains besides nitrogen, a stoichiometric mixture of sulphur dioxide and oxygen. This reaction is represented by the curves *S* and *S'*, Fig. 3, and we see that according to the quantity of gas, maximum yields of from 77 to 78% and from 90 to 91%, respectively, are reached. Exactly similar in behavior is a pure mixture of sulphur dioxide + oxygen; here too a quantitative conversion is impossible (curve *S*).

<sup>35</sup> German Patent No. 24,402.

If there is used, however, a gas mixture in which the oxygen or the sulphur dioxide is present in excess, it becomes possible by mass action of the one constituent to displace the other almost entirely from the mixture, by its combination with the corresponding quantity of the constituent in excess of the formation of sulphuric anhydride.

Every sulphuric acid contact process will then be the more successful, the more oxygen there is in the gas mixture in proportion to the sulphurous acid, while the nitrogen has no influence on the reaction.<sup>36</sup>

Let us consider now the behavior of a technical burner gas such as is obtained in roasting pyrites and in which the relation of the quantity of the sulphur dioxide present to the quantity of oxygen is as  $2\text{SO}_2 : 3\text{O}_2$ , corresponding to a composition by volume of 7%  $\text{SO}_2$ , 10% O, and 83% of nitrogen. If we allow this mixture to pass through an empty, uniformly heated porcelain tube, we perceive even under this condition the formation of some sulphur dioxide at certain temperatures, though it is very slight in quantity.

The results of this experiment are represented by the curve *P*, Fig. 3.

As a further experiment we fill the tube with a platinum contact substance, for example, platinized asbestos,<sup>37</sup> and now traverse all temperatures which need to be considered. With a rise of temperature the rapidity of the reaction increases, so that even at 380 to 400°C. nearly all the sulphur dioxide is found to be converted into sulphur trioxide. From 400 to 430°C. the reaction remains nearly uniformly quantitative, a conversion of from 98 to 99% being maintained; above this, however, there is a distinctly perceptible decomposition of sulphuric anhydride into the components, the curve falls again, though not as abruptly as it rose before. At from 700 to 750°C. only about 60% of the sulphurous acid is transformed into sulphuric anhydride, and at about 900 to 1,000°C. the curve reaches the zero mark, and no reaction between sulphur dioxide and oxygen can any longer be detected.

If we repeat this experiment under exactly the same circumstances but with smaller quantities of contact mass, or what amounts to the same thing,—with larger quantities of gas, we get a series of curves, 2, 3, 4, 5, 6 (Fig. 3), whose left and right portions have an entirely different appearance. For while the portions of the curves up to their highest points are approximately parallel to each other, they are seen to diverge somewhat if examined more closely, which points to a common origin; the decomposition side of the curves converge and finally all unite at about the same temperature, between 900 and 1,000°C. the zero point of the reaction.

If we follow the highest points of the curves, we notice a peculiar movement of their maxima with decreasing quantities of platinum in the direction of an increasing temperature and likewise a marked decrease in the highest attainable percentage of sulphuric anhydride formed. If these maxima are connected by a curve, this will on the left systematically approach the theoretically possible

<sup>36</sup> The formula  $\text{SO}_2 + \text{O} = \text{SO}_3$  accordingly does not express the conditions existing here, but should be written,  $2\text{SO}_2 + n\text{O}_2 = 2\text{SO}_3 + (n-1)\text{O}_2$ , where *n* should not be less than 2.

<sup>37</sup> For such an experiment there should be taken such a quantity of from 5 to 10% platinized asbestos that there is about 0.5 g. platinum in the farther half of the tube, while the first half remains empty and serves to preheat the gases.

conversion of 100%, while on the right its direction is toward a point in the neighborhood of 600°C. The convergence of the curves on the decomposition side leads to the conjecture that the decomposition of sulphurous anhydride becomes more and more independent of the contact substance that is used and develops into a function purely of temperature.

The correctness of such a conjecture could be tested very simply by a repetition of the experiment with the platinum left out, but for this test the mixture of gas must previously be brought into a condition of an almost complete conversion of the sulphurous acid into sulphuric anhydride before beginning the experiment.

This experiment was tried with a very surprising result. A curve was obtained which is moved to the right by several hundred degrees and falls strongly only at from 800 to 900°C. without, however, completely reaching the zero point at the temperature of from 1,100 to 1,200°C. which was at our disposal.

**Isochronal Curves of the Reaction  $2\text{SO}_2 + \text{O}_2 \rightleftharpoons 2\text{SO}_3 + 22800 \text{ Calories}$**

**FIG. 3.—CURVES OF REACTION OF SULPHURIC ACID FORMATION UNDER VARIOUS CONDITIONS.**

The once formed sulphuric anhydride, therefore, is very stable at high temperatures in the absence of contact substances. Consequently we have here an unstable equilibrium which is quickly destroyed by any contact substance and tends to become a stable equilibrium. The curve *E* shows this influence by the gradual approach of the curve *D* toward *S* when the same experiments as those giving curve *D* were tried but with a tube filled with fragments of porcelain. These phenomena call to mind those of overfusion and of delay in boiling of liquids heated above their boiling points. Porcelain and other substances evidently seem to act as catalysors, very much as does platinum, at these temperatures. Still it is very remarkable that at the high bright red temperatures that were used, a condition of unstable equilibrium should not become one of stable equilibrium more readily.

The formation of sulphur trioxide, as shown by curves, 1, 2, 3, and 4, is

dependent upon the length of time of contact of the gases with the contact substance.

A very simple means of getting a clear view of the changes taking place in the conversion is obtained by representing the results for different lengths of time isothermally, *i.e.*, by letting the *X* axis represent length of time, or what comes to the same thing, the quantity of platinum, and the *Y* axis the quantity of sulphur dioxide converted into sulphur trioxide.

In this way a group of curves (Fig. 4) is obtained, which shows at a glance the length of time or the quantity of platinum necessary for a certain percentage of conversion at a certain temperature. The form of the curves shows further that these begin at zero and continue indefinitely, being parallel to the *X* axis and symmetrically approaching the maximum corresponding to that particular temperature.

It is further shown that with rising temperatures and with increasing con-

FIG. 4.—ISOTHERMAL CURVES OF THE REACTION  $2\text{SO}_2 + 3\text{O}_2 \rightleftharpoons 2\text{SO}_3 + 3\text{O}_2$ .

ent of sulphuric anhydride, the curves turn more and more, thus deviating more and more from a complete conversion. Finally, the speed with which the reaction begins becomes so great that the first portion of the curves almost coincides with the *Y* axis at higher temperatures. The first meeting of the burner gas with the contact mass must be accompanied then by a very violent reaction, and here takes place the great rise in temperature of the first portions of the contact mass which may become heated to redness, depending on the manner of exterior cooling. It follows further from these curves for this very reason, that with the formerly generally used red heat of the contact furnaces a quantitative reaction was impossible, and it is only sulphur trioxide itself that exerts a retarding influence on the speed of the reaction.

As the important result of these experiments, a line of stable equilibria is shown which divides the whole range of temperatures into two divisions. Temperatures below  $200^\circ\text{C}$ , and above from  $900$  to  $1,000^\circ\text{C}$ , may be regarded as resulting, technically, in no reaction; between  $200$  and  $450^\circ\text{C}$ , the reaction of for-

mation preponderates, while above this the decomposition of the sulphuric anhydride rapidly becomes prominent.

Important technical conclusions can be drawn from these facts, for, even if the boundary line *A* has been determined for a particular technical gas mixture, the various modifications occurring in practice will scarcely have a very great influence in the position of this stable equilibrium. Further it is evident that this boundary line must theoretically and practically be independent of the kind of contact material; from which it follows, that only such contact substances will be capable of bringing about an approximately quantitative reaction in a single operation, as have their highest activity at the temperature of the zone of formation, that is under about 450°C. All contact substances that develop their maximum power only beyond this temperature will never be able to bring about a quantitative yield, however long they remained in contact with the gases.

At present there is only one contact substance which fulfills these conditions, namely, platinum; nor can this be replaced by any of the other metals of the platinum group even with approximately good results.

At the close of my lecture may I be permitted to present to you the development in the manufacture of sulphuric acid that has taken place in the works of the Badische Anilin & Soda Fabrik alone since the discovery of the contact process which I have described. The yearly production of sulphur trioxide by this concern has been as follows: 1888, 18,500 tons; 1894, 39,000 tons; 1899, 89,600 tons; and 1900, 116,000 tons.

For the development of such an enterprise the energy of any single individual would, of course, have been insufficient. The powerful assistance was necessary of a concern such as the Badische Anilin & Soda Fabrik, guided by the foresight of a Heinrich Brunck, the wide experience of a Gustav Jacobsen, and the expert assistance of prominent engineers was necessary in order to achieve the success which I have described and which is an honor to our national industry.

#### LABORATORY DETERMINATIONS.

*Melting Points.*—To determine the melting points, a glass cylinder containing the acid and a movable thermometer graduated to tenths of a degree, was immersed in a cooling bath. First were noted the temperatures to which the acid could be cooled with stirring without freezing (overcooling) (see accompanying curve, Fig. 4). As soon as the first crystals were formed, the cylinder was removed from the cooling bath and, with continual stirring, the highest temperature was noted to which the thermometer rose to remain constant even with the further formation of crystals. (Melting temperature, see table.) Then the crystals were again melted by careful warming and the temperature noted at which the last portions melted. (Higher melting-point curve, Fig. 4.)

*Specific Gravity.*<sup>38</sup>—Method: Weighing with brass weights in air at 15°C. in a narrow-necked graduated flask containing 500 c.c. which had been calibrated by weighing with water at 15°C. (I was assisted by Dr. Seitz and Dr. Slama in these determinations.)

<sup>38</sup> See also Lunge & Isler, *Lunge's Handbuch*, 1893, p. 107, and W. Kohlrausch, *Wiedemann's Annalen*, 7-69, 1883.

*Specific Heat.*<sup>39</sup>—Method: The calorimeter consisted of a vessel of sheet zinc protected against radiation by means of felt and containing 2 kg. water at room temperature (about 18°); about 1 kg. of the acid to be examined was warmed in a flask to something over 35°C. with shaking (calibrated thermometer reading 0.1° was used) and then quickly immersed in the calorimeter water and allowed

<sup>39</sup> Values for watery sulphuric acid, see *Lunge's Handbuch*, 1893, p. 123.

cool to 25°C., again with shaking, and then removed from the calorimeter. The temperature measurements in the calorimeter were taken with a Beckman's thermometer divided into 0.01 of a degree, the scale of which had been tested for correctness. The indicated temperature was corrected by the temperature difference in the different parts of the calorimeter and flasks used.

Example: 1 kg. oleum, 70% free SO<sub>3</sub>, was cooled from 35 to 25°C. in 2 kg. water. There were found in four experiments changes in temperature of:

2.41°C., 2.41°C., 2.41°C., and 2.42°C.; average, 2.4125°C.

Multiplying.....2.4125×2=4.825 calories.

Correction for calorimeter +0.045

4.8700

Correction for flask.....-0.1500

Specific heat.....0.4720 at 35°C.(to 25°C.)

(a) Values interpolated.

*Heat of Solution.*—Method: The calorimeter consisted of a glass flask of about 1 liter capacity, set up to its neck into a vessel of sheet metal, carefully insulated by means of felt and containing from 5 to 6 kg. of water at room temperature

from 18 to 22°C.). The whole apparatus could be lifted by means of the sheet metal vessel and shaken. According to the concentration of the acid from 40 to 100% of acid were used which were sealed up in a thin walled glass bulb ending in two capillary tubes. After breaking off the two capillary ends the acid was allowed to flow out under the surface of the water in the calorimeter as quickly as possible, being forced out by means of dry air if necessary. Finally the glass bulb with the capillary tubes joined to it were quickly broken and thrown into the calorimeter. The apparatus was then shaken up and the highest temperatures

read by means of a Beckman's thermometer divided into hundredths of a degree. Corrections were made for the water equivalent of the calorimeter and for the heat of solution of the acid.

thermometer. The weights were not reduced to a vacuum because the error amounted to less than 10% of the experimental error. Two titrations of the acid, independent of each other, were made and the average taken.

Example:—

In determining the heats of solutions of solid oleum which however solidifies

completely only at temperatures lower than the room temperature, the loss of heat due to this cause was of course included in the calculations.

The determinations were also made on a large scale. A wooden cask or heater

head having a capacity of 500 liters was filled with 400 liters of water and closed by means of a wooden cover. The weighing was done on a platform scales which had been calibrated. The water in this calorimeter remained constant in temperature for a very long time after having been stirred with a wooden stirrer.

FIG. 5.—APPARATUS FOR MEASURING ELECTRIC RESISTANCE OF SULPHURIC ACID. A corresponding quantity of acid about 1 or 2 kg., was then added and the temperature taken with a Beckman's thermometer divided into hundredths of a degree. The results of these two methods corresponded very well, and so have

not been kept separate. It may be stated however that the methods of determining the heats of solution on a large scale is much simpler, and if the weighing is sufficiently close, at least as accurate as the ordinary method on a small scale.

**Electrical Resistance.**—The measurements of the electrical resistance of sulphuric acid was made in the usual manner with an alternating current and a Wheatstone bridge with telephone, in an apparatus of glass with electrodes of circular platinum plates 4 cm. in diameter and 1.5 cm. apart. The arrangement of the parts of the apparatus is shown by Fig. 5. In order to be able to empty and wash the apparatus most conveniently, a glass stopcock was attached at the bottom. The distance between the electrodes was made constant by means of platinum wires attached to them and melted into a U-shaped piece of glass tubing

It was possible to measure differences of 0.02 ohm with sufficient accuracy. For monohydrate a slight deviation from the values given by Kohlrausch<sup>40</sup> was found, the maximum resistance being at from 99.9 to 99.95% H<sub>2</sub>SO<sub>4</sub> instead of a from 99.74 to 99.75% H<sub>2</sub>SO<sub>4</sub>. For these determinations the purest obtainable sulphuric acid, made from gaseous SO<sub>3</sub> was used. Otherwise the figures agree well with those of Kohlrausch. The determinations have been extended to 100% SO<sub>3</sub>. These measurements were made in company with Dr. Bazlen.

<sup>40</sup> Particular attention is called to the exact investigations by W. Kohlrausch in *Wiedemann's Annalen* 17-69, 1893.

*ive Effect upon Iron.*—For these experiments there were used prismatic 10×10×10 mm., whose surface had been planed and smoothed. After

ed from grease by means of caustic soda and alcohol, they were dried icator, weighed and laid for 72 hours in the acid whose corrosive effect

was to be determined. Then the acid was poured out, the rods washed with an excess of soda solution, hot water and alcohol, and carefully rubbed off with a cotton cloth. They were then dried in a dessicator and finally weighed. The

experiments were carried out together with H. Schulze, Dr. Scharff and Dr. Slama.

*Boiling Points.*—The temperature indicated at the first ebullition by a ther-

mometer dipped into the liquid was taken as the boiling point. If the liquid is allowed to boil with a reflux condenser, slightly higher values are obtained.<sup>4</sup>

<sup>4</sup> See also Regnault *Annalen d. Chim.*, 15-179, and Lunge's *Handbuch*, 1893, 122-123.

*Vapor Tension.*—Method: The vapor pressures of watery sulphuric acid were found in the ordinary manner by measuring the depression of the mercury

column of barometer height at various constant temperatures. With fuming acids this method cannot be used, the free sulphuric trioxide attacking the mer-

cury. The measuring was therefore done in an iron apparatus by means of a manometer which method is probably sufficiently accurate for practical purposes.

VAPOR TENSION OF VARIOUS FUMING SULPHURIC ACIDS (75% VOLUME OF ACID  
AND 25% VOLUME OF AIR).

*Viscosity.*—Method: The acid was drawn up to the work in a cylindrical glass tube containing 320 c.c. narrowed at the top and having a diameter of 28 mm. The acid was allowed to flow out through a short opening about 1.75 mm. in diameter. The time taken for equal volumes to flow out was

measured by means of a watch registering quarter seconds. The temperature was almost constant at 23°C. during these experiments.

*Capillarity.*—The rise in capillary tubes was measured in flat capillary tubing used for thermometers, carefully cleaned and dried for each determination; the

heights were measured in dry tubes and also in tubes previously moistened with the same acid that was to be tried. In most cases these determinations agreed

to each other. Where differences existed the height for the moistened capillary was taken as the correct one. The tube had a lens-shaped cross section.

### CAPILLARY ATTRACTION OF ORDINARY AND FUMING SULPHURIC ACIDS.

## TALC AND SOAPSTONE.

THE production of fibrous talc in 1901 was 69,200 short tons, valued at \$483,600, showing a large increase compared with the figures for the previous year. The production of common talc during 1901 is included with soapstone; the output in 1900 was 7,770 short tons (\$60,217). The output of soapstone amounted to 28,643 short tons (\$424,888), against 18,956 tons (\$189,560) for the preceding year.

### PRODUCTION AND IMPORTS OF FIBROUS TALC AND SOAPSTONE IN THE UNITED STATES. (IN TONS OF 2,000 LB.)

| Year.    | Production.   |           |         |              |          |         |            |            |         | Imports. (b) |         |         |

| 1899.... | 57,120        | 272,595   | 4.77    | 6,671        | 51,763   | 7.71    | 20,011     | 180,504    | 9.47    | 254          | 3,534   | 13.91   |
| 1900.... | 45,000        | 236,250   | 5.25    | 7,770        | 60,217   | 7.75    | 18,956     | 189,560    | 10.00   | 79           | 1,070   | 13.50   |
| 1901.... | 69,200        | 483,600   | 6.99    | (c)          | (c)      | (c)     | 28,643     | 424,888    | 14.83   | 2,396        | 27,015  | 11.32   |

(a) In reporting the value of their output of soapstone producers generally give the figures for the finished articles which they make. Since a varying proportion of labor enters into these, such figures are apt to be misleading. Few producers are able to name a value of the crude stone, or roughly dressed blocks. We have therefore valued the material arbitrarily at this stage at \$10 per ton, except in 1898 when a large production of inferior stone reduced the average. The value in 1899 is that reported by the producers. (b) Talc, ground, powdered or prepared. (c) Included with soapstone. (d) Includes common talc.

*Fibrous Talc.*—The larger part of the fibrous talc production continues to come from St. Lawrence County, N. Y., and its use for incorporation with paper pulp is increasing. A consolidation of a number of small properties will in all probability develop an increased production during 1902. Fibrous talc also is largely used for paint and plaster for walls.

*Talc and Soapstone.*—The bulk of the Virginia output of soapstone is manufactured into articles of utility by the producers. Considerable amounts of the North Carolina talc found its ultimate usage in paper making. There was a large increase in the output of pyrophyllite soapstone from Moore County, N. C. during 1901. The greater part of the talc which is used for the manufacture of pencils, and of coal and acetylene gas tips, is obtained from Swain County, N. C. This variety of talc commands the highest prices of any in this country. There appears to be an increasing demand in the United States for talc suitable for grinding to flour.

## TIN.

As in previous years, there was no production of tin in the United States during 1901. Some experimental work was carried on in the Black Hills, South Dakota, and at one prospect near Oreville five tons of selected ore was concentrated to 1,361 lb. of tin oxide (cassiterite) which contained gold to the value of \$10. The total value of the product was reported to be \$1,525. The process consisted of heap roasting with wood fuel, dry crushing to 60-mesh size and concentration on Wilfley tables. Several hundred tons of low-grade ores have been mined for exploitation purposes, but as yet the tin industry in the Black Hills has not been placed on a commercial basis.

The separation of tin from tin-plate scrap was continued during 1901 by the Vulcan Detinning Co., which early in 1902 was capitalized at \$3,500,000 to acquire the Vulcan Metal Refining Co., of Sewaren, N. J., and the Vulcan Western Co., of Streator, Ill., the production of both plants during 1901 being about 500 tons of pig tin. The production of The Ammonia Co., of Philadelphia, from scrap tin during 1901 was about 75 tons of pig, which was chiefly converted into chloride of tin. The production of the Johnston & Jennings Co., of Cleveland and Chicago, from scrap tin was about 250 tons, partly made into pig and partly into tin oxide.

(a) From Report of Secretary of Mines and Agriculture of New South Wales, which is the only Australian colony that produces metallic tin. Tin ore is also exported from New South Wales. Tin ore is produced in Victoria, Queensland, South Australia, and Western Australia, but its metal contents are reported in the productions of other countries.

(b) From the *Statistisches Jahrbuch des K. K. Ackerbau-Ministeriums*. The tin production of Austria is derived partly from domestic ores, and partly from Bolivian ores and impure tin from the East imported for refining.

(c) Total sales in Holland and Java as reported by William Sargant & Co.

(d) Exports of tin and tin in ore from Bolivia to England and the Continent. Some of this tin may be produced in Peru. It is all exported through Peruvian and Chilean ports.

(e) From *Mineral Statistics of the United Kingdom*. These figures give the amount of tin estimated to be obtainable in smelting the ore of domestic production. They differ considerably from the figures used by William Sargant & Co., which are possibly obtained directly from the smelters.

(f) From *Vierteljahrs und Monatshefte zur Statistik des Deutschen Reichs*. By far the larger part of this production is from Bolivian ores.

(g) From the *Resume Statistique de l'Empire du Japon*.

(h) According to export returns. Small amounts produced by natives for domestic consumption are not included.

(i) From official returns furnished by the Portuguese Government. The figures for 1896 include tin ore.

(j) From Russian official reports.

(k) The figures represent sales in Holland, reported by De Mouchy & Havelaar and W. Sargant & Co.

(l) Shipments from the Straits to Europe and America, as reported by William Sargant & Co., and to India and China by Boustead & Co., except the figure for 1890, which is taken from the *Report of the Governor of the Straits Settlements*.

(m) From *Report of the Secretary of Mines*.

(n) It will be observed that this table differs from the statistics usually referred to for the world's production of tin, namely, those of William Sargant & Co., and of the *Metallurgische Gesellschaft Frankfurt-am-Main*. This is because (1) they reckon Australian shipments to Europe and America, instead of the Australian production, whereby a good deal of Australian tin consumed at home is not included; (2) shipments from the Straits to India and China and the production of several minor countries are not included. A small amount of tin produced in Spain is necessarily omitted, owing to the absence of statistics for that country.

(o) In cases where the statistics in the above table have been taken from official sources, wherein values of product have been stated, a calculation of unit values has been made. This developed some amazing differences, which are undoubtedly due to making value calculations at different stages of the product; i.e., more or less cost of carriage is included.

(p) Statistics not yet published.

*Alaska.*—A discovery of stream tin on Buhner creek, 10 miles east of Cape Prince of Wales, in the York gold field has been made. Two to three feet of gravel overlie the bed-rock which consists of arenaceous schists, often graphitic and graphitic slates. The stream tin is concentrated on the bed-rock with small amounts of magnetite, limonite, pyrite, fluorite, garnets and gold. A second locality is on the Anaovik river, into which Buhner creek flows, and is about 0.5 miles from the latter deposit. Recoveries of from 150 to 200 lb. of cassiterite per cu. yd. are reported.

**AUSTRALASIA.—New South Wales.**—The total value of the tin produced in New South Wales in 1901 was £77,315, as compared with £142,724 in 1900, and £90,482 in 1899. The tin mining suffered greatly from drought in 1901, and to a less extent by the lower prices for the metal. The number of men employed on the alluvial and other deposits during 1901 was £1,428. The principal lode mine continues to be the Ottery, in the Emmaville district.

(a) From the annual metal circular of William Sargent & Sons. (b) Not classified for 1901.

**Northern Territory.**—Lode and stream tin are found in workable quantities at Mount Todd and Horseshoe creek. Several hundred weight which averaged well in value were shipped out to Sydney early in 1902 and a number of parties are prospecting. The stream tin runs from pieces the size of shot up to 7 to 8 lb. in weight.

**Queensland.**—The value of the production of tin in Queensland during 1901 was £93,723, as compared with £74,041 (1,141 metric tons of dressed tin ore) in 1900. Early in 1902 the main shaft of the Great Northern Freehold Tin Mine, at Heberton, was completed, the latter part of the sinking passing through very favorable tin formations. The Smith's creek tin mine, seven miles from Mount Garnet, is said to have a lode 30 ft. thick yielding 30% of 70% ore on its 24-acre lease. A company capitalized at £7,200 has been organized to operate

the property. The prospecting of the New England mine on Smith's creek, near Mount Garnet, appears to have been of a favorable character, specimens of the 40 to 50 lb. weight of stream tin 70% pure having been obtained. In the latter half of 1901 the Vulcan tin mine, at Irvinebank, crushed 2,097 tons of stone for a yield of 181 tons of black tin, valued at £6,793, and £1,650 was declared in dividends. A new power battery has been erected, which is expected to increase the output.

*South Australia.*—The production of tin ore in South Australia was 17 metric tons, valued at £774 in 1900, as compared with 2 statute tons, valued at £180 in 1899.

*Tasmania.*—The output of tin ore was less in 1901 than in the preceding year. This unexpected result being due principally to the poorer quality of the ore raised from the Mt. Bischoff mines, the most productive in the State. The mining in the St. Helens district is principally alluvial, among the companies operating being the Royal Ruby Tin Mining Co., Thureau's Deep Lead Tin Mining Co., the Upper Ruby, the Rose Tin Co., and several smaller companies. The Scamander Tin & Gold Mining Co. was recently organized to treat by hydraulicking the extensive alluvial flats on the banks of the Scamander river for the recovery of gold and tin. The Briseis mine, on the Ringarooma river, owned by the Venture Corporation, has constructed a water supply race 3 ft. deep by 6 ft. wide, by 30 miles in length, to insure a water supply during the dry season. By means of this head of water the basalt overburden is removed at a cost of 2d. per cu. yd., and the tin drift somewhat cheaper. The amount of tin ore recovered from the drift is estimated at about 0·8%, and an output of from 150 to 200 tons per month is anticipated. Across the Ringarooma river the Ringarooma Tin Mining Co. has installed a 1,000-H.P. pumping plant which has been for some time hydraulicking the overburden with good prospects of success. The Pioneer Co. works a flat deposit by means of a 250-H.P. engine, at a cost of £10 per H.P., and sand-pump placed on a flat boat, which is floated into position, and the water then pumped out until the boat rests on the bottom. The drift in this mine is first sluiced down by water under several hundred feet of pressure, and then elevated by a pump nearly 80 ft. to a tail race; 1·5 cu. yd. of drift per minute are raised, using about 40 cu. ft. of water, and over 40 tons of tin ore, valued at £70 per ton are secured per month. The Anchor Tin Mine, Ltd., has had under construction during 1901 a 39-mile water race, which is to be extended to the South George river, tapping the Waratah creek and the North George river on the way. The cost of this improvement is expected to be about £15,000 when completed about June, 1902. The ore is of very low grade, but apparently inexhaustible in quantity. It is anticipated that the entire mill of 100 stamps will be run by water power when the same is available. Early in 1902 a plan for the reorganization of the company was proposed. The issues of first debentures aggregating £15,000 at 7%, and the second debentures aggregating £10,000 at 10%, were consolidated into first debentures at 7·5% per annum. The new corporation of the same name is to be capitalized at £120,000, against the previous capitalization of £150,000, and a call of 5s. per share, which will realize £28,500, was issued, the which, after paying outstanding debts, was esti-

ated to provide £14,000 for working capital. The percentage of tin extracted since 1898 has ranged from 0·32 to 0·38%. Tests by the Government Assayer of the tin ore from the deposits on Schouten Main yielded by assay from 1·2 to 4% tin, the ore occurring in tin granite. Tests made of the alluvial from the Schouten Main Mining & Dredging Co.'s claims averaged 2 lb. tin or 2·86 lb. tin ore (at 70%) per cu. yd. The deposits would pay with careful management. The Mt. Bischoff Mining Co. during the six months ending December 31, 1901, smelted 1,416 tons of concentrates yielding 980 tons of tin; of this 633 tons, yielding 440 tons of tin was smelted on account of the company. The accounts at the end of the year showed a credit balance of \$234,015 after distributing \$200,695 in dividends and writing off various amounts at the rate of 20% for depreciation. The average percentage of concentrates obtained from the ore was 1·312%, and the total output from the foundation of the company up to December 31, 1901, was 59,656 tons.

*Western Australia.*—The total quantity of black tin mined during 1901 amounted to 734 tons, valued at £40,000, against 824 tons, valued at £56,702 in 1900. The output of the Greenbushes mining district during 1901 was 321 tons, valued at £18,852, while that of the Marble Bar district was 413 tons, valued at £21,148.

*Bolivia.*—One of the most important tin mining districts in Bolivia is that of Huanuni, where the ore occurs in numerous veins and lodes traversing the granitic country rock. Most of the veins are very rich in ore, but considerable difficulty is experienced in extracting the tin on account of the extreme hardness of the veins and the adjoining rocks. A considerable amount of tin pyrites is found, from which the tin is extracted by calcination and subsequent grinding and washing. About 10 miles south of the Huanuni are the Challa Apacheta mines, which are opened on several lodes, one of which is remarkable for its extent, the veins being from 25 to 30 ft. in width. The tin ore is found here in granular form interspersed through an argillaceous matrix, which doubtless represents the weathered product of original vein materials. In the Ouroro district, which exported 8,177 metric tons of tin ore in 1900, is the Avecayo deposit, while to the east of this district are the mines of Berenguela, both of which yield considerable quantities of ore. The exports of Bolivian tin from Antofagasta, Chile, during 1900 were 8,721 long tons of small tin bars, valued at £195,271; 2·75 long tons of tin, valued at £520; and 76 long tons of tin minerals, valued at £370.

*France.*—Small veins carrying cassiterite are known to occur near Vaulry, on the Limoges-Bellac railway, and have been worked from time to time without however attaining the position of an established enterprise. Recently a new company—the Société des Mines de Vaulry et Cicux, secured a concession of alluvial ground near by from which it is producing some ore. The method of extraction includes washing of the gravels and concentration on Wilfley tables.

*Malay Peninsula.*—The total output of tin for 1901 was 46,984 long tons, against 42,442 long tons in 1900. The increased price of tin during all of 1900 and the early part of 1901 stimulated production in fields formerly abandoned as too low grade, and labor was plenty during both years. The production of the

individual Federated Malay States for the years 1900 and 1901 will be found in the subjoined table:—

| Malay States.     | 1900.      |              | 1901.      |              |
|-------------------|------------|--------------|------------|--------------|
|                   | Long Tons. | Metric Tons. | Long Tons. | Metric Tons. |
| Perak.....        | 21,166     | 21,506       | 22,920     | 23,287       |
| Selangor.....     | 16,041     | 16,298       | 18,018     | 18,306       |
| Negri-Sembilan... | 4,300      | 4,369        | 4,479      | 4,551        |
| Pahang.....       | 935        | 950          | 1,567      | 1,592        |
| Totals .....      | 42,442     | 43,123       | 46,984     | 47,736       |

The report for 1901 of the Pahang Kabang, Ltd., shows that while a profit of £786 was made on total receipts of £3,020, the average yield per ton of gravel or black tin was but 46·7 lb., or about the same as the recoveries at Dolcoath, Cornwall.

Late in 1901 the Tronoh Mines, Ltd., capitalized at £160,000 was registered to work mines at Tronoh. A full equipment of modern mining machinery will be installed.

A recent examination of the tin deposits of Johore results in the discovery of large tin fields in the vicinity of Ayer Puteh. While the surface tin is difficult to save by Chinese methods, owing to its fineness and association with iron, the coarser gravels near bed-rock are said to yield large recoveries.

*United Kingdom.*—The Dolcoath Mine, Ltd., during the second semester of 1901 earned a net profit of £16,274, against £16,902 for the previous half year. A call of 2s. 6d. was made on the partly paid shares, which increased the capital stock by £2,157 15s. A number of improvements were made in the mining and milling plants, which it is thought will increase the output of tin and at the same time reduce the working costs. From the total cash surplus of £17,024 10s. a dividend of £7,481 6s. was paid the shareholders, leaving £8,932 3s. to be written off capital account and £611 1s. to be carried forward. Its statistics of production for several years are given in the subjoined table:—

| Six Months.            | Tin Ore Crushed. | Black Tin Sold. | Product per Ton of Ore. | Average Value per Ton of Ore. | Average Price per Ton of Black Tin. | Amount Realized. |

#### THE TIN MARKETS IN 1901.

*New York.*—The tin market maintained its reputation as a center for speculative trading, and the prices, as in previous years, showed extensive fluctuations which were not traceable to any corresponding change in the statistics. In fact the supplies of the metal apparently exerted little influence on quotations in times of heavy buying or depression from outside sources. To a large degree the market

freed itself from the influence of silver prices. Consumption throughout the year was heavy, with only short interruptions on this side of the Atlantic, our market very often moving entirely independent of that of London. Futures could at nearly all times be bought at a discount. On the other hand, the scarcity of labor caused by the Chinese war, which made itself felt last year to the detriment of the production in the far East, was followed by an abundant supply.

The year opened rather dull, spot tin selling at about 26·50c., and consumers and speculators not taking much interest in the article. By the middle of March prices had declined to 25·5c. Business then became more brisk, and stimulated by speculative buying the market advanced to 28·50c., which was the closing quotation at the end of May. It kept steady throughout the month of June at about that figure. Somewhat later, the steamer *Asturia* with 750 tons of tin aboard foundered, and the London market was practically cornered, spot tin over there at one time selling at £140, and three months at £123 15s., a backwardation of nearly £17. A sharp decline abroad carried prices down also in this country, and during August spot tin could again be bought at 26·5c.

During September, the strike at the mills of the United States Steel Corporation exercised a depressing influence on the market. In view of the heavy fluctuations in London and the large backwardation manufacturers allowed their stocks to run down and confined their purchases to their immediate requirements. With spot tin ruling at a premium of from 1 to 2c., quotations nevertheless steadily declined until 24·5c. was reached the beginning of November. About the middle of the month, the lethargy which had prevailed for such a long time gave way to considerable activity. The steel strike came to an end, and while the consumption apparently was very large, the available supply in sight was quite small. This caused prices to advance by leaps and bounds, and during the last few days of November it developed that the market to all intents and purposes was cornered. Some belated bears had to pay 33 and 35c. to cover their commitments. These extraordinary conditions were soon followed by a sharp reaction. The East was selling freely at the high values which had been established; several overdue steamers arrived with large quantities of tin aboard, and in sympathy with the heavy decline in copper, prices suddenly broke to 25c. About the middle of December, the failure of one of the most prominent operators on the London Metal Exchange was announced, and another heavy decline set in, spot tin selling at 23c. Consumers bought freely at this figure, and the year closed with spot tin selling at 23·37@23·75c. and futures at 23@23·25c.

*London.*—At the commencement of 1901, the statistics showed a decrease, ex-

cluding American, of 2,132 tons, and a total visible supply of about 23,000 tons. In the latter part of December, 1900, the price rose to £124 in anticipation of large American purchases, but buying declined toward the close of the year, and January opened with the market at £122 10s. for all positions, but prices gradually dropped to about £118. Toward the close of the month, however, business was fairly active, and £123 17s. 6d. was touched for close dates. Forward tin was freely offered, the month closed at £121 5s. cash and a backwardation of £4 on three months. Statistics at the beginning of February showed a further decrease in European stocks of 396 tons, but supplies during January had largely exceeded the demand, and the total tonnage in sight was increased by 1,600 tons. On the strength of the above European figures the month opened with prices at £123 for early deliveries; the backwardation on forward increasing to about £5. Toward the middle of the month prices declined, and the closing quotations were £121 cash and £115 12s. 6d. three months. March opened with a decrease of 786 tons in European stocks and a further addition to the total visible supply. Heavy arrivals in London eased spot prices, and values gradually sank to £118 10s. for early dates, £115 for end of April and £113 7s. 6d. for three months. The end of the month saw prices at £115 5s. for cash and £113 for three months, with a dull tendency. Consumptive demand was very small in Europe, but a large quantity of arrival tin was taken out of the English market for shipment to America. In the early part of April sellers were persistent, and in spite of good orders from America values fell away until £113 15s. cash and £111 5s. three months was touched; the downward tendency being assisted by the increase in European stocks of 1,316 tons. Later in the month a good consumptive demand came to the assistance of the market, and prices reached £115 15s. cash and £113 10s. three months. After numerous but small variations in price, final quotations stood at £118 cash and £115 three months. Consumptive demand was good throughout the month both at home and from America. The figures at the opening of May showed a decrease of 3,725 tons in English and Continental stocks. The market opened firm at £118 7s. 6d. cash and £115 for three months, increasing later to £120 10s. for cash and £118 for three months. Eastern sellers were scarce and consumption remaining good, the bulls easily manipulated a rise of £4 per ton for all positions. Toward the end of the month the position became still firmer and the market went up to £130 for cash and £129 5s. for three months. In view of the approach of the Banka sale, however, interested parties endeavored to check the upward rush, and, with an easier feeling apparent in Eastern offers, May ended with prices £129 15s. prompt and £128 10s. for forward. A characteristic of the month was the smallness of the London spot stock, and this gave great assistance to bull operations. The Banka sale realized an average of £129 15s. Consumption was good throughout and tin-plate makers were very busy. Three months tin gained altogether £7 during the month and at one time the backwardation had almost run off. At the beginning of June statistics showed an increase of 2,083 tons in European stocks and prices slowly receded to £127 10s. cash and £124 10s. for three months. A renewal of the American demand strengthened the prices, which jumped to £131 10s. cash with a £4 backwardation on forward. The middle of the month witnessed a keen struggle for

the mastery between bulls and bears, and finally the bears brought three months tin as low as £122 5s. with cash at £127. The loss of the *Asturia* with 750 tons for New York revived prices and the final tone of the market was firm with cash at £129 5s. and three months at £123 and £123 5s. Demand from consumers was sluggish and a good deal of speculative option business was transacted. The East was for the most part a free seller, and a large business was done, but toward the close of the month the tone in this quarter became firmer. The first portion of July was chiefly marked by a great scarcity of warrants for immediate delivery. European stocks decreased 475 tons and business started at £130 10s. for cash. Transactions in three months were very restricted. London spot stock was tightly held, and some buyers had to pay fancy prices in order to cover their obligations. In one case as much as £140 was paid for a parcel of cash tin. Heavy bear selling of forward tin increased the backwardation on three months; at one time this stood as wide as £20 to £25. With large arrivals of metal, prices of cash rapidly fell, and finally closed at £116 for cash and £112 for three months. Consumption on the whole was not very good, most users buying from hand to mouth. Welsh tin-plate makers were very busy owing to the strike in America and bought fair quantities. The Banka sale at the end of the month realized an average of £118 5s. The statistics published at the commencement of August showed an increase of 2,300 tons in the total visible supply and of 3,000 tons in European stocks. The market started firm at £121 7s. 6d. for cash and £117 5s. for three months, but values gradually declined to £116 cash and £113 three months. Extensive realizations forced prices still further down; at one time cash was quoted at £114 and three months at £110 7s. 6d. In the latter part of the month cash tin became scarce and £116 10s. was touched. As the month drew to a close the market was very firm at £118 cash and £115 for three months. A large quantity of tin was shipped to America and there was a good demand from tin-plate makers both there and in this country. The first of September figures were favorable, the decrease for the month being 1,768 tons in European stocks, and the market opened strong at £118 7s. 6d., and £115 three months; later prices steadily receded until £113 15s. for cash and £110 15s. for three months was quoted. Some speculative purchases revived the market slightly, but with the East selling freely and bad reports from America prices slowly sank. The decline was also assisted by the collapse in the copper market. The last week in the month witnessed a general steadying up of prices, and the final quotations were £113 5s. to £113 10s. for cash and £111 10s. for three months. The European demand was fairly good, but there was a serious shrinkage in American consumption of tin for tin-plates due to the steel strike. An increase of 1,005 tons in the stocks at the commencement of October caused somewhat heavy selling and values fell to £109 5s. cash with a backwardation of £2 on three months. Later purchases of cash continued until £115 10s. was paid, but as soon as buying orders ceased prices collapsed, and £112 cash was touched, while forward tin remained unchanged. The latter portion of the month was dull and prices finally closed with cash at £114 to £114 10s. and three months £106 to £107. Demand from home consumers was quiet, but during the first portion of the month America made extensive purchases, the tin-plate works being very busy owing to the ter-

mination of the steel strike. There was no Banka sale during October and the beginning of November figures showed a decrease in European stocks of 1,035 tons. The opening was dull with cash tin fluctuating between £114 and £115, and a backwardation for forward of £5 to £6. Values slowly weakened to £111 10s. cash, with three months at £106 15s. The strong reports from America due to the scarcity of spot tin there strengthened the market and £114 5s. was paid for near dates. In the last week of the month prices were further assisted by bulls calling in cash tin and £118 cash was touched. Realizations, however, quickly followed and the final tone was dull with cash at £113 and three months at £105. The American market throughout the month was considerably above the English level, and at one time prices for immediate delivery touched £156. December commenced with an increase in the visible supply of 2,250 tons, excluding America, and this fact, coupled with the weakness in copper, caused a dull tone throughout the month. On December 20, when it was announced that a large bull operator had suspended payment, there was a rush to sell by people who had to deliver metal to him at higher prices, which caused a very quick break in prices, so that £98 was touched for cash, £97 10s. being accepted for three months. When the most urgent selling had spent itself there was a quick recovery to £101 for cash and £100 for three months. Notwithstanding the continual fall in prices the demand for tin-plates remained good, and the prevailing weakness seems to have arisen more from the growing idea of increased production than of a falling off in consumption. The closing quotations are given as £105 7s. 6d. to £105 10s. for spot, and £104 to £104 2s. 6d. for three months.

## TUNGSTEN.

THE production of tungsten ore in the United States during 1901 amounted to 179 short tons of concentrated ore, valued at \$27,720 (which was derived from 1,221 short tons of crude ore), as compared with 220 tons of concentrated ore in 1900. The tenor of tungstic acid in the ore ranged from 60 to 70%, and the value of the high quality ore ranged from \$102 to \$333 per ton, averaging \$154.86. During 1901 there were produced in the United States 76,000 lb. of tungsten metal, 13,000 lb. of ferrotungsten and 3,000 lb. tungstic acid and sodium tungstate amounted collectively to 92,000 lb., as compared with the reported production of 172,000 lb. of tungsten and tungsten salts during 1900. The price of tungsten metal varied from 58c. to 64c. per lb. and ferrotungsten from 27c. to 31c. The price of tungsten ore of from 45 to 55%  $\text{WO}_3$  is about \$2 per unit, while ores of from 65 to 75%  $\text{WO}_3$  content command from \$2.50 to \$3 per unit if free from sulphur and phosphorus. The bulk of the output during 1901 was derived from Colorado, although small quantities were produced from the mines near Lead City, So. Dak., and Long Hill, Conn.; 2,918 tons of crude ore were recorded as having been mined in 1901. Until recently the sources of supply of tungsten ores for the United States were England, Austria-Hungary, Saxony, Germany, and Australia. The growing domestic demand for tungsten to be used in the manufacture of self-hardening tungsten steels has encouraged the exploration for tungsten minerals and the development of the many reported deposits may lead to the replacement of the imported ferrotungsten alloys by those produced from domestic ores. This is particularly pertinent as tungsten minerals in some localities occur with gold and silver ores and the metal may be produced from them to commercial advantage.

The chief use of tungsten is in the use of self-hardening tungsten steel, the metal being used either as ferrotungsten or as the powdered metal. Recently it has been added with very satisfactory results to a copper-aluminum alloy in order to impart greater strength and toughness. It is claimed that the self-hardening property of steel, ordinarily obtained by the addition of tungsten to chrome-steel, may also be obtained by the addition of molybdenum, and in the latter case but one-half the quantity, as compared with tungsten, is needed to produce the same effect. The alloy known as tungsten-ferro-chrome was imported into the United States during 1901 to the value of \$9,839, Germany supplying the bulk of the import.

Calcium tungstate is used in the Roentgen ray apparatus on account of its fluorescence. Sodium tungstate is used to fasten the color of certain cotton goods and to render textile fabrics noninflammable. It has also been used to color glass and to some extent in the manufacture of stained paper.

*Arizona.*—Tungsten ores occur in considerable quantity in the Arivaca district, Pima County, and near Benson, in the Dragoon Mountains, Cochise County. A tungsten ore deposit has been developed 60 miles south of Hackberry, Mohave County, where a seam of wolframite from 2 in. to 6 in. wide occurs in a vein of quartz which varies from 1 ft. to 3 ft. in width. Several tons of ore averaging about 70% tungstic acid were mined but not shipped.

*Colorado.*—Wolframite and huebnerite ores occur in quantity in Boulder, San Juan, Gilpin, Ouray, and Lake counties. During 1901, however, Boulder County was practically the only producer, the output aggregating 65 tons, averaging 60% tungstic acid and valued at \$8,775. The average price received per unit was \$2.25, which is equivalent to \$135 per ton. San Juan County contributed a small quantity of concentrated ore. The Great Western Exploration & Reduction Co., of Boulder, has been recently organized to mine tungsten ores and to manufacture ferrotungsten. It proposes to concentrate the ores from 20 to 1 and 3 to 1, which will yield concentrates of from 60 to 68% tungstic acid.

*Connecticut.*—The American Tungsten Milling & Mining Co. has done a small amount of development work at Long Hill, Fairfield County. According to Prof. William Hobbs the scheelite and wolframite occur more abundantly at the lower contact of the intruded beds of crystalline limestone in the diorite and hornblende gneiss of the locality. The mill tests show the proportion of scheelite in the vein to approximate 5%.

*Nevada.*—Over 1,000 tons of huebnerite ore have been mined at the deposits in the foothills near the base of Wheeler Peak, 12 miles south of Osceola, White Pine County. The formation for several thousand feet up the mountain side is of granite overlain by Cambrian quartzite. There are five prominent veins in the granite which have been traced to the contact with the quartzite but none occurs in the latter. The huebnerite vein in the tunnel dips 65° N.W. and is from 18 to 36 in. wide. The ore occurs in crystals up to 3 in. in size in white quartz, although much of the mineral is in fine grains and in irregular bodies. In one locality scheelite also occurs in the ore. Small quantities only of pyrite and fluorite occur as associated minerals. Practically all of the ore shipped has been hand sorted and cobbled or concentrated to an average of 68%  $WO_3$ . Hand concentrated samples have averaged as high as 67.5%  $WO_3$ .

*Oregon.*—The scheelite deposits in the Virtue district, near Baker City, Baker County, are reported to carry considerable free gold. The vein material at the water level consists almost entirely of scheelite.

*Washington.*—The wolframite deposits in Steven County have been exploited to the extent of running in a 50-ft. tunnel upon the vein which is reported to be 4 ft. in width, dipping at about 75°. The wolframite crystals occur disseminated in quartz and specimens were obtained up to 1 lb. in weight. Gold and silver

are associated with the wolframite, but in too small quantities to warrant the working of the property for them alone.

*Other States.*—Tungsten ore deposits occur also in Oregon, Idaho, Montana, New Mexico, South Dakota and North Carolina. A few tons only for experimental purposes have been produced from these sources during 1901.

*Australia.*—The production of tungsten ore in Queensland during 1900 amounted to 192 metric tons, valued at £6,605. South Australia contributed 9 tons and Tasmania 18 tons to the total output. A reported discovery of a scheelite deposit in New Zealand was made early in 1902. The lode is stated to be 4 ft. wide and to average 25% scheelite together with 0.65 oz. gold per ton. It is claimed that the ore can be economically concentrated to from 70 to 75% mineral which contains about 80%  $\text{CaWO}_4$ . Scheelite is mined to some extent at Macrae's, Island of Otago, which is the only locality in the colony supplying a merchantable product.

*Chile.*—During 1900 there were exported from Antofagasta 125 long tons of wolframite, valued at £7,153, and 2 tons of metal, valued at £120.

#### TECHNOLOGY.

Lewis P. Hamilton and Edgar F. Smith<sup>1</sup> have made in an electric furnace a number of alloys of iron and rare metals, including several with chromium content up to 16%. Among these alloys are copper-chromium, copper-aluminum-tungsten, copper-molybdenum, iron-titanium-tungsten, iron-chromium-titanium, iron-columbian-tantalum and iron-columbium-tantalum-titanium.

The subjoined table gives the analyses of some of these alloys:—

| Component.            | 1     | 2     | 3     | 4     | 5     | 6     | 7     | 8     | 9     | 10    | 11    |

## ZINC AND CADMIUM.

THE production of zinc or spelter in the United States during 1901 was the largest annual output yet recorded, and amounted to 140,822 short tons, as compared with 123,231 short tons in 1900 and 129,675 short tons in 1899. The production by districts is shown in the subjoined table.

PRODUCTION OF ZINC IN THE UNITED STATES.

| States.                   | 1896.  | 1897.   | 1898.   | 1899.   | 1900.   | 1901.   |

The large increase in the production of zinc was due to the removal of the smelting plants to the Iola district in Kansas, where the cost of production is considerably less owing to the use of natural gas as a fuel. The output of zinc in Kansas during 1901 was 74,270 short tons, as compared with 57,276 short tons in 1900. A large quantity of zinkiferous lead ores from Colorado was smelted during the year and the zinc content regained. Formerly these low-grade zinkiferous ores were rejected as waste material. The output of the Illinois-Indiana district showed an increase over the preceding year in spite of the removal of a number of the smelting plants to Kansas. The production from this district in 1901 amounted to 44,896 short tons, as compared with 37,558 short tons in 1900. The combined output of the sole producer in the East, the New Jersey Zinc Co., and the chief producer of the South, the Bertha Mineral Co., was 8,603 short tons, as compared with 8,259 short tons in 1900. The ore supply for these works was derived from the mines in New Jersey and in southwestern Virginia. The Joplin district furnished ores for a large part of the Western smelters, although during the past year zinkiferous tailings and zinc ore have been treated in a few of the smelters in Illinois and a considerable quantity was shipped to Europe via Galveston and New Orleans, chiefly to the Vieille Montagne works.

Details of the progress in mining and metallurgy are given by Walter R. Ingalls later in this section under the title "Progress in the Metallurgy of Zinc in the United States during 1901."

**Zinc Oxide.**—The production of zinc white in the United States during 1901 was 46,500 short tons, valued at \$3,720,000, as against 48,840 short tons, valued at \$3,677,810 in 1900. The greater part of this output was made by the New Jersey Zinc Co., operating at Jersey City and Newark, N. J., Bethlehem and Palmerton, Pa., and Mineral Point, Wis. Page & Kraus, at St. Louis, produces annually about 450 short tons, and the United States Smelting Co., formerly the American Zinc & Lead Co., of Cañon City, Colo., manufactures a pigment called "zinc-lead," which is a mixture of oxidized compounds of zinc and lead. The production of this special pigment during 1901 was 2,500 short tons, valued at \$150,000. The Renfrew Zinc Co. put its new plant at West Plains, Mo., in operation in December, 1901, and the Ozark Zinc Oxide Co. is completing a new works at Joplin, Mo. The estimated annual capacity of each plant is 20,000 tons of zinc oxide. The G. & G. Zinc Oxide Co., which was formed at West Plains, Mo., in 1900, reported no production during 1901.

(a) Includes zinc oxide, 8,718,507 lb. (\$104,140). (b) Zinc oxide, 7,849,059 lb. (\$252,194). (c) Zinc oxide, 10,685,220 lb. (\$366,598). (d) Zinc oxide, 11,391,093 lb. (\$496,380). (e) Zinc oxide, 9,122,283 lb. (\$393,259.)

The use of zinc chloride for preserving railroad ties continues to be increased and it is estimated that the nine concerns engaged in this industry during 1901 consume 3,000 short tons annually.

The American Smelting & Refining Co., formerly producers of zinc sulphate as a by-product in smelting lead ores, reports no production during 1901. The Grasselli Chemical Co. is stated to have produced 5,000 lb. of zinc sulphate daily

during 1901. The manufacture of lithophone, which is a pigment consisting essentially of a mixture of barytes with zinc oxide and zinc sulphate, is being carried on to a considerable extent in the United States, chiefly by the New Jersey Zinc Co. and the Grasselli Chemical Co., the latter concern reporting a capacity of output of 10,000 lb. daily. The greater part of the output is consumed in the manufacture of glue and special paints.

*Colorado.*—According to the Hon. Harry A. Lee, Commissioner of Mines for Colorado, the production of zinc from the ores of that State during 1901 amounted to 13,427 short tons, of which Lake County furnished 11,583 short tons and Mineral County 1,044 short tons. These figures are based on the metallic zinc content of the ores produced. About 70% of the output was exported and 30% treated by domestic smelters, including ore used for the manufacture of zinc-lead pigment at Cañon City, Colo., and possibly some shipped to Mineral Point, Wis., for the manufacture of zinc white. In 1901 the Leadville mills produced 23,261 tons of concentrates averaging 45% Zn, 6% Pb, and 10% Fe. Besides the Leadville product there were also shipments of zinc ore from Silver Plume, Montezuma, Creede and other mining districts. Kansas smelters have received ore from Creede which has assayed as high as 59% Zn, 3.75 to 5% Pb, and about 2% Fe. The high iron content of the blende is due to the iron chemically combined which cannot be removed by any method of mechanical concentration.

The immense deposits of mixed lead and zinc sulphides at Leadville and Kokomo promise to become an important factor in the zinc industry in the near future. The ore is a silver-bearing mixture of galena, pyrite and blende, with very little gangue. As early as 1886 it was milled for its lead content and accompanying silver, the blende being accumulated in tailings heaps. Recently by the application of improved milling methods a closer separation has been obtained and a large quantity of this class of ore has been treated at Leadville, yielding a galena-pyrite concentrate and a ferruginous blende, the latter having a large sale chiefly to European zinc smelters, although a small quantity has been treated at the Kansas smelters. The freight from Leadville via Galveston to Swansea or Antwerp during 1901 was about \$9.50 per short ton, and while the miners receive \$5 to \$7 per ton it is purely a by-product, and the value of the remainder of the ore is increased by its removal. The Colorado Zinc Ore Co. and the New Jersey Zinc Co. are erecting magnetic separating plants at Denver and Cañon City, respectively, to produce ore containing about the same percentage of iron as that which the present concentrating mills are furnishing, but several units higher in zinc and lower in lead. These ores have been smelted direct in Sadtler retorts by the Midland Smelting Co., at Bruce, Kan. The American Smelting & Refining Co. is erecting a zinc smelting plant at Pueblo which will afford a local market for the blende concentrates of Leadville, Kokomo, Montezuma, Creede and other mining districts in the State. The United States Smelting Co. was organized during the year to take over the holdings of the American Zinc-Lead Co., formerly operating the Cañon City plant, which smelts chiefly low-grade zinkiferous lead ores, largely from Utah and Leadville.

the product is copper matte, containing the precious metals, which is shipped refined. The by-product consists of zinc-lead pigment used largely in the manufacture of paints. The United States Zinc Co., capitalized at \$2,000,000, is organized to build a large zinc plant near Pueblo, to handle Leadville zinciferous ores chiefly from the A. Y. & Minnie mine.

*Iowa.*—(By S. W. Beyer.)—The production of zinc in the Dubuque region has been reduced to inconsiderable proportions, a condition brought about largely by the sharp decline in the price of zinc, and to a less extent through the exhaustion of the ore bodies in sight. The weak demand and low price have held out no inducements toward the active prospecting and development of new properties as in the years 1898 and 1899. Ore was sold during 1901 at a price which would not cover the cost of production, let alone yielding a reasonable return to the operator. The entire output for the Iowa field scarcely reached 60 tons, principally carbonate, "dry bone," and sold at an average of \$7.70 per ton. The most select stock sold for \$12 per ton, yielding fair returns to the labor and capital employed, while certain low-grade ores were disposed of at 6¢ per ton, entailing a considerable loss to those concerned. Almost the entire output was shipped to Mineral Point, Wis. La Salle, Ill., may be considered as a competing market, but rarely affords active competition. The two largest companies remained practically closed or were only worked in a desultory way on account of legal complications. The Alpine Zinc Co. has abandoned the old workings, at least temporarily, on account of water, but has sunk a new shaft in the same vein several hundred yards to the westward, which promises well. A good body of high-grade ore is in sight and will be marketed as soon as the price warrants. The zinc industry in the Dubuque region gives little promise for the future unless prices strengthen materially. The plant of the Dubuque Zinc Concentrating Co. was idle during the year because of the intermittent and insufficient supply of crude ore and the general decadence of the industry.

*New Jersey.*—(Through the courtesy of Mr. A. Heckscher.)—In 1901 the mining operations of The New Jersey Zinc Co. have practically been confined to the Mine Hill deposit, near Franklin Furnace. At the southerly end stripping has been actively followed up and some 45,000 tons of limestone sold and shipped. That portion of the deposit between its southerly termination and the ridge dike, distant 700 ft. to the north, will probably be stripped and laid bare entirely during 1902. It will then remain to be determined whether stripping shall be carried farther to the north and to what extent. A very large body of ore will be laid completely open and ready for quarrying by the work now in hand. Operations at Mill No. 1 have now ceased and they may not be resumed for some time. It has been found that Mill No. 2 is much in excess of its former rated capacity of 1,000 tons in 24 hours, and it can crush, size and prepare for market readily 70 tons of ore per hour, or over 1,600 tons in 24 hours, which was assumed to be the maximum capacity. Some of the machinery better adapted for fine crushing has been installed and other minor changes ordered. The new mill operates very economically. The over-all cost, disposing of about 700 tons of ore in 10 hours in the most favorable month of the year, has been only 38¢ per ton. When it is borne in mind that the ore must be crushed, dried, sized,

cooled, fed to the Wetherill separating machines, and every grain of ore that responds magnetically must be lifted bodily from the conveying belt and carried out of the magnetic field, also that the tails must be jigged to remove the limestone from the willemite, the tails carried away and stored, the willemite again dried and all of the several products assembled in separate bins and shipped, it will be seen that only large capacity, not overstrained, and large output can admit of such low cost. It is believed that 40c. per ton, including repairs and renewals, should cover all costs of crushing, separating and shipping.

The Sterling Hill deposit has not been worked during 1901. The limits of the Franklin deposit are gradually being defined to the north, and this great lense of ore appears to close some 1,200 ft. underground somewhat in the shape of a submerged hammock. It is quite possible, however, that the ore will carry farther to the north than is now indicated by development work.

During the year several outside organizations have continued the active exploration of the belt of white limestone with diamond drills, both between Mine Hill and Sterling Hill and to the north of the larger deposit. Nothing appears to have been found excepting that at one or two points the diamond drill has pierced the magnetic vein which as a rule underlies the Franklinite deposits, but which also is much more persistent than the latter. When these drill records are published they will afford valuable information and will save the necessity of repeating work which is time-consuming and costly.

The output of raw ore from the mine has been as follows: To Mill No. 1, 65,480 long tons; to Mill No. 2, 123,994 long tons. The shipments have been from Mill No. 1, concentrates, 60,319 long tons; from Mill No. 2, crushed ore, not concentrated, 2,621 long tons, and concentrates, 108,016 long tons.

The new mill is operating admirably, and has more than fulfilled expectations. A separate paper by Mr. Stone, furnishing detailed information concerning the central manufacturing plant of the New Jersey Zinc Co., at Palmerton will be found elsewhere in this section.

There were 26,131 long tons of zinc ore, valued at \$657,140, exported from New Jersey during 1901, mainly via New York.

*Kentucky.*—For the six months ending December 30, 1901, the Kentucky Fluorspar Co., at Marion, Crittenden Co., shipped 1,136 short tons of zinc carbonate ore, valued at \$13.60 per ton f. o. b. Marion, to Mineral Point, Wis. No zinc blende has been marketed as yet. This is the first recorded shipment of zinc ore from Kentucky for commercial purposes.

*Missouri and Kansas.*—The production of zinc in Kansas and Missouri during 1901 showed a marked advance over that of the preceding year, the outputs being 87,353 and 77,414 short tons, respectively. The increase was due entirely to the output of Kansas, which was 74,270 short tons in 1901, as compared with 57,276 short tons in 1900, Missouri showing a decrease from 20,138 short tons in 1900 to 13,083 short tons in 1901. There has been no radical change in mining during the year, and a few new discoveries of ore were made southeast from Joplin toward Granby. The milling tendency is toward the production of the highest grade ore possible, and while the standard grade ore is 60% Zn and but 8% siliceous gangue, certain mills make a product assaying as high as

64.5% Zn. Magnetic concentration has been satisfactorily applied to ore high in pyrites and two new magnetic separators of the Cleveland-Knowles and the Waring types are being exploited with promising results.

At present the deepest deposit being worked in Missouri is 250 ft., while the average is about 100 ft. The record of prospect drilling in Missouri given in the following table is of interest:—

| Holes Drilled. | Depth. | Ore Found. | Holes Drilled. | Depth.  | Ore Found. | Holes Drilled. | Depth.  | Ore Found. | Holes Drilled. | Depth.    | Ore Found. |

The exports of zinc ore from the Joplin district during 1901 amounted to 13,294 long tons, valued at \$410,544, all shipped via New Orleans except 291 long tons via Galveston.

The center of the zinc smelting industry in Kansas is the Iola district, comprising Iola, Gas City and La Harpe. Outside of this district the only large smelter is that of the Edgar Zinc Co., at Cherryvale. The old plants at Pittsburg and Weir were idle during the year. A few furnaces have been operated at Girard and the small works at Bruce have smelted Colorado ore direct in Sadtler retorts.

Full details of mining and milling in the Joplin district are given in the separate article by Mr. Frank Nicholson later in this section. An unsuccessful attempt was made toward the close of 1901 to consolidate a number of the more important Western zinc smelting works under the name of the Zinc Smelting Corporation, with a capitalization of \$50,000,000.

*Virginia.*—The Bertha Mineral Co. now operates the only zinc smelting works in the South. The plant consists of 10 large, direct-fired, Welsh-Belgian

furnaces, pottery, kilns, roasters and necessary accessories. At these works the practice is maintained to a high state of efficiency, and while minor improvements have been made from time to time, no radical changes have been made for some years past. In common with Eastern zinc manufacturers, the competition of Western smelters using cheap natural gas fuel has been felt, but the superior purity of the spelter produced from the Southern and Eastern ores, as compared with that made in the West, together with its higher price has offset to some extent the advantage of cheapness of the Western product. There are only three active zinc mines in the South—the property of the Wythe Lead & Zinc Mine Co., at Austinville, Va., the Bertha mines, in Wythe County, Va., both quite well-known properties, and the Clark mine in Pulaski County, Va., an operation of more recent development; all of these mines are tributary to the Bertha Mining Co.

At Austinville, Va., work has been carried on actively during the year 1901, the chief output being zinc ore of the calamine variety, while lead carbonate and limonite iron ore have also been produced. Additional water power is being developed to be utilized for an electric haulage plant; in order to get at rich deposits of calamine it is necessary to strip about 15 acres of ground, carrying a clay over-burden from 50 to 100 ft. thick, and for this very large undertaking the new haulage plant is being added.

At the old Bertha zinc mines, the work of stripping the clay over-burden is being vigorously and constantly carried on. As this clay contains valuable limonite ore it is washed and the product shipped to blast furnaces in Virginia.

At the Clark mine, in Pulaski County, both iron and zinc ores are being produced. The minerals are so intimately mixed that it is necessary to separate them by magnetic treatment.

While the usual amount of activity in prospecting is noted, yet it may be positively stated that no new producing zinc mines have been developed in this part of the South. In the zinc belt near Knoxville, Tenn., there has, perhaps, been unusual activity, yet practically no shipping ore has been discovered in this territory. The ore found is of the disseminated blende character, occurring in magnesian limestone. While these deposits appear to be quite common and to cover a large territory, experience seems to indicate that, owing to their leanness, they cannot be worked profitably.

*Wisconsin.*—(By S. Weidman.)—The lead and zinc region of Wisconsin, which was described in THE MINERAL INDUSTRY, Vol. IX., comprises an area of about 2,000 square miles, in Iowa, Grant and La Fayette counties, in the southwestern part of the State. The main ore-bearing formation consists of a stratum of magnesian limestone, the Galena limestone, having a thickness of about 250 ft., lying nearly horizontal and forming the surface rock throughout the greater part of the region. The ores are also found to a minor extent in the limestone formation, the Trenton, and other formations of the Lower Silurian occurring at or near the surface. The vertical order of occurrence of the ore in the district is commonly as follows: Above the level of ground water the dominant valuable minerals are galena and smithsonite; with the galena there is some cerussite and less anglesite, and with the smithsonite there is some sphalerite. The smithsonite may locally

occur to a depth of from 15 to 30 ft. below the level of ground water. Below the galena and smithsonite, sphalerite occurs associated with marcasite.

It is the generally accepted theory that the material of these ores was originally widely dispersed through the sedimentary rocks, especially the limestone. By the action of the circulating ground water, ascending and descending through the crevices and openings in the rocks, the disseminated material of the ore was concentrated into ore bodies. The sheets of ore are found largely between the beds, in vertical and in inclined fissures called locally flats, openings and pitches. The ore bodies are usually connected with one another, and are of quite variable dimensions, ranging in thickness from a fraction of an inch to over a foot. Definite figures on the output of lead and zinc ore in Wisconsin for the past year are not available at the present time, but there is a general report of increased activity in mining throughout the year. A survey of the lead and zinc deposits of the State by the Wisconsin Geological and Natural History Survey is in progress at the present time.

At Mineral Point the New Jersey Zinc Co., operating the Grillo-Schroeder process, manufactured sulphuric acid grading from 66°B. to monohydrate and up to 40% of fuming acid. This company has licensed a plant at Repauno, and that of the Dupont Chemical Works, both on the Delaware river; also one in New Mexico, and a large plant on the Pacific coast.

(a) The statistics for Austria are taken from the official reports of the Mines Department, except for 1900, for which the figure reported by Henry R. Merton & Co. has been used.

(b) Official statistics, except for 1901.

(c) The statistics for the United Kingdom are arrived at by deducting the zinc produced from domestic ores, as reported in the official Blue Books, from the total output of the smelting works as stated in the reports of Messrs. Henry R. Merton & Co.

(d) Statistics not yet available.

(e) Statistics compiled from direct returns by the producers to THE MINERAL INDUSTRY.

(f) According to Henry R. Merton & Co., Belgium, Holland and the Rhine district of Germany in 1901 produced 303,474 metric tons of spelter, against 189,301 metric tons in 1900 and 192,904 in 1899.

THE WORLD'S PRODUCTION OF ZINC  
IN METRIC TONS

## THE SPELTER MARKETS IN 1901.

*New York.*—The market was very steady, being free from the wide fluctuations that have characterized former years. With the exception of a few isolated lots shipped on old contracts, no spelter was exported. The European market was not in a position to take additional quantities from this side without depressing prices still further, for in consequence of the lessened consumption European producers felt compelled to reduce production, in order to guard against a further decline in values. It seemed absolutely necessary for the foreigners to have recourse to such concerted action, in view of the fact that the spelter industry had entered a phase which meant severe losses. The unprecedented advance in the price of coal and the higher rate of wages which were established during the last two years, added heavily to the cost of producing the article, and the result was in most, if not all cases, that producers were doing a losing business. Under these circumstances it was a matter for congratulation that our domestic demand proved fully sufficient to absorb the entire production of the United States. In spite of the steel strike, the galvanizing industry, which forms the principal outlet for the consumption of the metal, was very active with but short interruptions. The sheet zinc business was satisfactory in price as well as volume, and the brass trade consumed considerably more than in any previous year. The many avenues through which spelter enters into use for electrical purposes, such as telegraph and storage batteries, called for larger quantities, as did also the industries in which zinc oxide seeks its outlet. On the other hand, the output of zinc ores continued very large, although several of the companies floated a year or two ago, met with disaster. While some shipments of Joplin ores were made to the other side, mainly with a view to stimulating competition, the capacity of the smelting plants now in operation is more than sufficient to treat the present output. Colorado has supplied a moderately large tonnage of ores and indications are that shipments from that direction will show a large increase during the coming year. January opened rather dull at about 4.125c. New York, consumers pursuing a hand-to-mouth policy, but producers not pressing sales. As the year progressed, the market weakened, in spite of a shut-down of about 60% of the mines and a good consumption; and 3.75c. St. Louis and 3.95c. New York was reached by the middle of February. From this figure there was a slight recovery, only to give way to renewed depression. During April, however, some speculative buying set in and the market displayed considerable activity. Quotations of 3.875c. St. Louis and 4.05c. New York was reached in June. During the summer months, the steel strike prevented any undue upward movement,

and it was not until the middle of September that matters began to improve. A lively demand developed for early shipments and prices advanced to 4'25c. New York in October, and 4'325c. in November. The closing figures at the end of the year were 4'15c. St. Louis and 4'3c. New York, with stocks in first hands comparatively small. Negotiations were undertaken with a view to a consolidation of the principal smelting works, but the plan did not materialize.

*London.*—January opened with a steady market at £18 17s. 6d. for ordinaries, and £19 for specials. There was a fair amount of buying by consumers, but toward the end of the month the American dealers showed themselves willing to sell at the European parity, and this caused values to recede to £18 5s. for ordinaries. Continental makers also sold freely, thus helping the fall. February again witnessed a further shrinkage, owing to a continuance of Continental offers, but America was somewhat better and offering from that quarter ceased. Values continued to drop throughout the month, until it finally closed at £17 5s. Consumers bought freely throughout, having good orders placed, principally in the galvanizing and kindred trades. March was also to be a month of declining rates, and although consumers were tempted to buy ahead and book good quantities, their purchases were not enough to stem the tide of selling, which set in from Europe, where all makers seemed to be rather heavily stocked. The lowest figure touched this month was £16 for ordinaries, specials being held for about 10s. more. Just at the close of the month there was a rally, chiefly induced by speculative buying and a withdrawal from the market of some of the chief sellers. The close was consequently strong at £16 17s. 6d. ordinaries, and £17 for specials. April commenced with a quiet tone and prices drifted back again to the region of £16. At this time there was a meeting of the principal producers on the Continent to come to some arrangement, whereby they might restrict output and so keep values from declining. This caused a quick reaction from the bottom, and £17 2s. 6d. was paid for ordinaries. This conference was postponed constantly throughout the remainder of the year, but no definite agreement was come to. Continental producers took the opportunity of clearing out good quantities at these figures, which led to a set-back early in May to about £16 18s., only to advance again rapidly to about £18, but a further reduction was apparent toward the end of the month, when the ruling figure was £17 15s. for ordinaries and £18 for specials. Consumers bought freely throughout in the hopes that a speedy arrangement would be arrived at by the producers. Zinc sheets and galvanized iron were in good demand, large orders for the latter article being placed for the South African market. June, until about the middle of the month, was very quiet, but a little buying kept the tone steady at about £17, but toward the end of the month a quick break occurred, owing to heavy pressure of Continental sales, so that when July began the value of ordinaries was no more than £16 10s., specials being held for about 5s. more, and the market was steady throughout the month, prices only fluctuating to the extent of a few shillings, closing figures being practically those last mentioned. August opened with a fair inquiry at about £16 10s., but steady buying caused a revival to about £17, which was about the nearest price when the month ended. September saw values steadily maintained within 5 shillings either way of £17, and although consumers were busy,

there was enough spelter offering from the Continent to keep values from rising much. All the upward movements in October were induced by rumors as to the success of the Producers' Convention, but no confirmation of any agreement was forthcoming. Prices oscillated between £16 18s. 9d. and £17 2s. 6d., and closed about the lowest. November opened with a quiet market and a falling tendency, most producers seeming quite willing to meet the demand at current values. Business was done as low as £16, and as high as £16 17s. 6d., but the end of the month witnessed the lowest figure. December found spelter depressed in sympathy with all other metals, and prices dropped to £16 5s., but rallied toward the middle of the month, on the renewed reports that the European producers had at last come to a definite understanding. The highest point reached was about £17 for ordinaries, specials being held for about 5s. advance, and a good business was done on the advancing market, but when the above figure had been reached there was a tendency to recede, caused, no doubt, to a great extent, by the depression in the other branches of the trade. The year closed with good ordinaries selling at £16 15s., and specials at £17.

*Breslau.*—The quarterly average prices of spelter during 1901, as reported by the Royal Mining Office at Breslau, were as follows, the quotations being in marks (23·8c.) per 50 kg.

|                     | 1895. | 1896. | 1897. | 1898. | 1899. | 1900. | 1901. |

The production of crude zinc was 107,967 tons, valued at 34,636,000 marks; of metallic cadmium, 13 tons. The output of calamine was 219,332 tons, of blende 253,770 tons; while from the furnaces 3,013 tons of zinc sponge (Schwamm) and 3,604 tons of ashes, oxide and waste were recovered. The consumption of coal was 1,160,052 tons.

#### A REVIEW OF PROGRESS IN THE METALLURGY OF ZINC IN 1901.

BY WALTER RENTON INGALLS.

THE last year was characterized by the introduction of numerous improvements in the metallurgy of zinc, which tend to cheapen the cost of production and render available supplies of ore that have not been capable of profitable exploitation heretofore, without there having been any radical innovation. About the same number of new processes for the treatment of mixed sulphides has been patented as in former years, but in so far as practical results are concerned the satisfactory solution of this problem appears to be as far away as it was at the beginning. Messrs. Ashcroft and Swinburne have been continuing in England their experiments with the Phoenix process of electrolytic smelting, with successful results it is claimed, but so far they have not gone beyond the experimental stage; especial interest is attached to their proposals because of the novelty of their nature. In the meanwhile progress is being made in the distillation of charges high in iron and lead by the ordinary method of zinc smelting, with subsequent recovery

of a portion of the lead and silver values from the residuum, which procedure, aided by the more perfect preliminary preparation of the mineral that can in many cases be effected by means of the Wetherill magnetic separators, constitutes a real advance in the art.

**ECONOMIC CONDITIONS.**—There was an important increase in the production of spelter in the United States; the output of Europe increased also, the production of Upper Silesia having advanced from 102,213 metric tons in 1900 to 107,045 metric tons in 1901, which was an unusually large gain for that district, while the output in Rhenish Prussia, Westphalia, Belgium and Holland jumped from 189,311 metric tons to 202,485. Increasing production in Europe in the face of the generally depressed industrial conditions, especially in Germany, caused the price of spelter to rule low (the average for the year was only £17 0s. 6d. at London) and the cost of coal continuing high, the production of spelter could hardly have been conducted there on a satisfactory basis. In the United States the consumptive demand was sufficiently large to absorb the entire domestic production at a higher scale of prices than prevailed in Europe and there was consequently no exportation of spelter from this country in 1901, save the comparatively small quantity of high-grade Eastern spelter, which is shipped abroad under any circumstances.

**Closing of Old Works.**—The year 1901 witnessed what is practically the end of the direct-firing coal smelteries of Missouri and Kansas, at least for the present or so long as the natural gas holds out. Several of the old plants which were closed in 1900 were dismantled and others are being permitted to fall gradually to pieces through idleness and decay; there is little likelihood that any of them will be of further use in their present form. The few coal smelteries that were in operation during 1901 comprise the works at Collinsville, Ill. (which were closed in August), the Carondelet works of the Edgar Zinc Co., and the small plants at Bruce and Girard, Kan., and Rich Hill, Mo. It may be remarked incidentally that the works at Girard and the two plants of the Edgar Zinc Co. are controlled by the United States Steel Corporation, which obtains therefrom about 25,000 tons of spelter per annum, or about 50%, more or less, of its own requirement of spelter for galvanizing purposes. The great center of the Western zinc smelting industry is now the Iola district, comprising the environs of the town of Iola, Kan., and the near-by towns of Gas City and La Harpe. Outside of that district the only large smelting plant in Kansas is that of the Edgar Zinc Co., at Cherryvale.

**New Plants.**—The Lanyon Zinc Co. and George E. Nicholson, both at Iola, and the Edgar Zinc Co., at Cherryvale, added new furnaces to their plants in 1901. A new plant of 1,800 retorts was erected by A. B. Cockerill, at Gas City, near the existing plant of the Prime Western Spelter Co. Another new plant, comprising a sulphuric acid department, was erected by the Standard Acid Co., at Iola, near the Nicholson works. The ore is to be roasted by means of a modification of the Hegeler furnace and the acid department is designed to turn out a product of 60°B. strength. The United States Zinc Co., composed of interests which are important in the American Smelting & Refining Co., made arrangements for the erection of a zinc smelting plant at Pueblo, Colo., which will afford

a local market for the blende concentrate of Leadville, Kokomo, Montezuma, Creede, Rico and elsewhere in Colorado. The Lanyon Zinc Co. and the New Jersey Zinc Co. built rolling mills during the year (at La Harpe, Kan., and Palmerton, Pa., respectively) which will begin operation in 1902. The outcome of the advent of these concerns into the sheet zinc business, wherein the Matthiessen & Hegeler Zinc Co. and the Illinois Zinc Co. have heretofore had an extremely profitable monopoly, is awaited with interest.

*The Palmerton Works of the New Jersey Zinc Co.*—The new plant of the New Jersey Zinc Co., at Palmerton, Pa., which has been under construction for several years, was described recently by Mr. George C. Stone, the chief engineer of the company.<sup>1</sup> This is not only the most modern, but also is the most comprehensive works for the treatment of zinc ores in the United States. The plans of the company contemplate an ultimate capacity for producing annually 60,000 short tons of zinc oxide, 30,000 short tons of spelter and 72,000 long tons of spiegeleisen. In addition to those departments there is a sheet zinc rolling mill, a catalytic sulphuric acid installation, and a lithophone plan of five tons capacity per day.

The works are situated on the edge of the anthracite coal field, about 9 miles east of Mauch Chunk. The ore, coal, limestone and other supplies are delivered by the Central Railroad of New Jersey to the zinc company, which does its own switching. The cars are passed over an all-steel, 100-ton track scale, or over a turnout which avoids the scale, to a double track trestle, the latter rising at a 2% grade for 1,000 ft. and extending 2,000 ft. further at an elevation of 30 ft. above the ground level. The space under the trestle is occupied by bins, each 20 ft. high and 25 ft. wide, which have chutes, accessible from cross-galleries, for the delivery of coal and ore into wheelbarrows. South of the trestle there is a storage yard, 100×2,000 ft., which will hold 60,000 tons of ore, and a like quantity of coal; this yard is commanded by a Brown traveling bridge, which will take material from the bins to any part of it, and vice-versa.

The zinc oxide plant is located north of the trestle. The furnace house is 50×1,260 ft., and contains 288 furnaces, built back to back in blocks of 12, each block being an independent unit. North of the furnace house are the blower houses, one for every two blocks, each containing two blowers driven by directly connected motors. North of these are the settling towers and exhaust-fan rooms, each of the latter containing eight directly driven fans. Still further north are the bag-rooms, of which there are four. The bag-rooms have an aggregate floor area of nearly 2 acres (87,120 sq. ft.) and contain over 27 miles of bags, which have a total surface of 850,000 sq. ft. The bag-rooms occupy three sides of a rectangle, the packing house filling up the fourth side. The packing house is 32 ft. wide and 143 ft. long, four stories high. The first and fourth floors are for the storage of unpacked oxide. The latter is lifted by an electric elevator to the top of the building, whence it is led through chutes to bolting machines on the third floor and thence to packing machines on the second floor. Bags are sewed and cleaned on the third floor. North of the packing house there is a rooperage building and four storehouses, the latter having an aggregate floor area

<sup>1</sup> *Engineering and Mining Journal*, April 5, 1902.

of 63,000 sq. ft. and capacity for 9,000,000 lb. of oxide. The cooperage building is 82×160 ft., two stories high. The lower floor is used for stock storage and drying rooms; the barrels are made on the upper floor and are conveyed thence over bridges to the packing house. Automatic sprinklers safeguard the building against fire.

The oxide furnace house is built entirely of iron and steel. The working floor is 10 ft. above the ground level, affording room for collecting hoppers for the residuum, which is drawn from them into steel cars and trammed by locomotives to the spiegeleisen department. The fan rooms and blower houses have brick walls and steel, trussed roofs.

East of the oxide department is the power plant, which is centrally located with respect to the entire plant. The boiler house lies just to the north of the trestle, its south side serving as a retaining wall for coal dumped from the trestle. The coal is drawn through openings in the wall and discharged directly in front of the boilers. The boiler house is 56 ft. wide and will be eventually 320 ft. long. It now contains 16 return tubular boilers, each 6 ft. in diameter and 20 ft. long, equipped with Wilkinson automatic stokers and arranged also to be fired with the waste gases of the blast furnaces. The engine house, which is situated north of the boiler house, is 64×270 ft., the main floor being 10 ft. above the ground level. A 40-ton crane traverses the entire building and a standard gauge track runs into it. The walls are of brick; and the roof slate, laid on 3-in. plank, carried by steel trusses. There are now installed two Dickson-Corliss horizontal, cross-compound engines, each of 800 H.P., directly connected with a 600-kw. (250 volts) Crocker-Wheeler generator. There is room for another generating set of the same type. Two 150-kw. Crocker-Wheeler generators, directly connected with Payne horizontal, tandem compound engines are in reserve. There is also room for three blowing engines, of which only one has yet been installed; this is a horizontal, cross-compound Southwark-Corliss, with 26-in. and 46-in. steam cylinders, 54-in. air cylinders, and 48-in. stroke.

The spiegeleisen blast furnaces are situated east of the power plant. Room has been provided for four, but only one has yet been built. This is 60 ft. high with bosh 14 ft. in diameter. A Brown automatic hoist and charging apparatus is used. Upright flue-dust catchers are installed in duplicate. South of the furnace are five 32-pipe Cooper stoves, one of them being held in reserve. Then follows the stock house, containing 18 circular steel tanks, set on concrete walls, for the storage of fuel and limestone, a steel trestle extending over them.

The spelter department is placed to the east of the spiegeleisen furnaces. At present it comprises two large regenerative gas-fired furnaces, which are erected in a brick building, with steel truss roof, 66×240 ft. The working floor is 14 ft. above the ground level, this arrangement conforming to the latest tendency in such installations. North of the furnace house are 11 Taylor gas producers, in a steel building 43×91 ft., and a boiler house, 54×60 ft., containing two 250-H.P. Babcock & Wilcox boilers for blowing the producers and heating the retort drying rooms. There are also annealing furnaces, clay sheds and a pottery, the last being provided with hydraulic presses. South of the spelter plant are the sulphuric acid and lithophone departments.

The works are equipped with an elaborate system of tramways, water supply and electric lighting; and also with a very complete installation of construction and repair shops.

*The Census Report.*—Bulletin No. 124 of the Twelfth Census, entitled "Lead, Copper and Zinc Smelting and Refining," has recently been issued. The statistics collected for it cover the calendar year 1899; unfortunately the conditions of that year in so far as the zinc smelting industry is concerned were peculiar and abnormal, which fact must be borne in mind in considering its statistics. The latter are reported by States and include the returns of smelters who produce zinc white, sheet zinc and sulphuric acid besides spelter, wherefore a purely technical analysis of the data is limited to results of comparatively little value. The statistics as reported by the Census, with the interpolation of some averages, are summarized in the following table:—

|                                              | United States.    | Illinois.        | Indiana.       | Kansas.          | Missouri.      | Pennsylvania.    | Other States. <sup>a</sup> |

(<sup>a</sup>) Includes two works in New Jersey and one each in Virginia and Wisconsin. (<sup>b</sup>) Includes the value of land, buildings, machinery, tools and implements and the live capital utilized, but does not include the capital stock of any corporations reporting. (<sup>c</sup>) Values at the works where produced. (<sup>d</sup>) Includes women and boys, of whom the number is insignificant; does not include proprietors, managers, superintendents, clerks and messmen. (<sup>e</sup>) Cost delivered at the works. (<sup>f</sup>) Does not include selling expense, interest on capital or amortization of plant.

The above works produced only spelter, no by-products being recovered. Under the caption of fuel, the coal and coke used for reduction material is doubtless included, although not so stated in the report. It is not stated what value, if any, is put on the natural gas consumed.

The production of the works of Indiana, Kansas and Missouri and the labor and fuel cost per ton of spelter, segregated according to the fuel used, is given in the table on the following page.

| Natural Gas. |                         |                   |                  | Coal.                                                            |                         |                   |                  |

Referring to the first table, it is to be remarked that the great difference in the values of the spelter produced in the East and the West, *i.e.*, 6.65@6.90c. vs. 5.10@5.55c. per lb., is due partly to the superior quality of the former metal. Also it is to be borne in mind that there were wide fluctuations in price in 1899 and the period of the year at which the product was sold would make a great difference. In the latter half of the year most of the Western smelters were operating at a greatly reduced rate and some closed their works entirely.

**BLLENDE ROASTING.**—In the blende roasting practice in the West conditions remain the same as heretofore, some of the works employing long mechanically-raked furnaces and some of them continuing to use hand-raked shelf burners. The new works of the Standard Acid Co. has a modification of the Hegeler furnace, which is adapted to utilization of the sulphurous gas for acid manufacture; the new plant of A. B. Cockerill has hand-raked shelf burners. The cost of roasting with the aid of natural gas in the Iola district, both with hand-raked and mechanically-raked furnaces, is phenomenally low; in the former, the work is done by contract at 5c. per 100 lb. of roasted product, or \$1 per ton, at which rate the men earn \$2@2.20 per day, according to the season of the year. (In the cool weather the men roast more ore than in the extremely hot weather of the Kansas summer.) A cost of \$1 per ton of roasted ore corresponds to approximately 85c. per ton of raw ore, dry basis.

Numerous new mechanical roasting furnaces were patented in 1901, none of them being designed especially for blende roasting, however, with the exception of that which was invented by Mr. Joseph P. Cappeau, general manager of the Lanyon Zinc Co. and was put in practical use at one of the Iola works of that company. This furnace is more or less a modification of the Ropp furnace; the space under the hearth is entirely clear, however. The patent specifications claim: "A roasting furnace comprising a hearth supported on standards to permit free circulation of air beneath the floor of said hearth, an opening in said floor for permitting the passage of air into the hearth, and adjustable means for controlling the passage of air through said opening."<sup>2</sup> The new Spirek furnace, which was designed originally for the reduction of quicksilver ore, has been adapted to blende roasting, and an installation for that purpose has been made in Italy, as is described later in this section.

**DISTILLATION FURNACES.**—The type of distillation furnace that is most economical depends greatly upon the kind and cost of the fuel that is available. In Europe, where coal is dear, the tendency of the last 10 years has been toward the introduction of Siemens regenerative furnaces. In Upper Silesia, the number of them at the older works has been increased, and the latest works, *i.e.*, the Bernhardihütte (1897) and the Florahütte (1900) have nothing but them. In Bel-

<sup>2</sup> United States Patent No. 691,112, Jan. 14, 1902.

gium the same tendency is manifested, the old furnaces that have been lately torn down at some of the works there having been replaced by Siemens massives with 240 large retorts. Such furnaces are now in use at Overpelt, Prayon and Engis. This is rather a reversal of opinion, because the Siemens system was early tried with the Belgian type of furnace and did not find favor. In the United States, where coal is generally very cheap, there is less incentive to economy in its use, although gas-firing may be advantageous in other respects. Siemens furnaces were built about 1880 at Rich Hill, Mo., Pittsburg, Kan., and Peru, Ill. The last is the only place where they are in use in the West at present. At Lasalle gas-fired furnaces, with partial recuperation of heat by means of stoves and by the generation of steam for power, have been employed for a long time. In the natural gas fields, so long as the supply of that wonderful fuel continues plentiful and cheap, there is no inducement to build expensive, heat-recuperative furnaces.

*Iola Furnace.*—The Iola smelters have settled upon a type of forced draft distillation furnace, which was originally adapted from the long furnaces employed at Lasalle, Ill.; after many vicissitudes and reconstructions, it has been modified so as to give satisfactory results with natural gas firing. At Cherryvale alone furnaces operated by natural draft are employed, following the type adopted in the Indiana gas field, but better designed and more substantially constructed. The Indiana type was tried experimentally at Iola, but has been discarded in favor of the forced draft furnace, or “blow” furnace, as it is commonly called.

The distillation furnaces now commonly in use at Iola comprise from 600 to 660 retorts, arranged in five rows of 60 to 66 each per side. The introduction of any portion of the gas through the end wall of the furnace has been discontinued, and the entire supply is now fed in through ports in the alternate pillars of the working sides of the furnace, the gas being brought down through branch pipes from the mains extending along the furnace for the full length of each working side. The omission of four tiers of retorts at one end of the furnace (in order to afford the gas and air formerly introduced at that end of the furnace an ample opportunity for mixture before reaching the retorts) has also been abandoned, and in those furnaces previously constructed in that manner the former open space is now occupied by additional retorts, wherefore a furnace that used to contain only 620 retorts now has 660. The old furnaces have also been generally repiped, giving them a larger gas supply, a better distribution of gas and better means of regulating its influx, together with that of the air for its combustion, and consequently a better control of the temperature. The result of these improvements has been a complete elimination of the old trouble of soot deposition, which was, of course, due simply to a deficiency in air supply or to imperfect admixture of the air and gas, while a uniform temperature throughout nearly the whole length of the furnace is attained and can be maintained as desired, of course with a beneficial effect upon the yield of metal obtained from the ore. Not less in importance is the better systemization of the labor in distillation, which has enabled the maneuver, *i.e.*, the discharging and recharging of the retorts and the accessory processes, to be performed within the customary limit of five hours, or in but little excess over that time.

The physical construction of the furnaces has also been improved, many of the older ones with entirely too light walls and imperfect bracing having been torn down and replaced by furnaces of more substantial and better ironed masonry. This has led naturally to an increased length of furnace campaign. It is probably still too early to determine what will be the average duration of furnace campaign at Iola, inasmuch as gas smelting there is not yet more than five years old and it is only within the last two years that the practice has definitely crystallized, but there seems to be no reason why the average should not exceed two years and with good construction in the first place and subsequent careful attention it may be fully three years. The form of furnace with a single, large, light and airy ash-tunnel is generally adopted, none but the furnaces at La Harpe having two tunnels, but the chimneys instead of being built in connection with the end wall of the furnace, resting on the arch of the ash-tunnel, as was the case of some of the earlier furnaces, are now set a few feet in advance of the end wall and offset from the prolongation of the center lines of the combustion chambers, so that they stand on a solid foundation independent of the furnace proper and at the same time leave the ash-tunnel clear, connection between the combustion chambers and their respective chimneys (two per block) being made by short horizontal flues. Another detail in which there has been a change is the removal of the gas regulator to a point 40 or 50 ft. outside of the furnace house, the advisability of this change having been indicated by the explosion of a regulator in one case, ignition of the escaping gas and destruction of the furnace and house; formerly the regulators were frequently contained in a small lean-to directly connected with the furnace house.

The furnace houses are designed after the same general type throughout the district. This is a long frame building with a simple pitch-roof supported by posts (no trusses) which are disposed in such a way as to leave an ample clear space in front of the furnace. The distance from the working faces of the furnace to the sides of the building is sufficient to enable work to be done with comparative comfort notwithstanding the intense radiation of heat from the long furnaces. The floors of the buildings are paved with brick and the ore is brought in by means of large charging cars on tracks extending in front of the furnace on each side. Movable shields to aid and protect the men in working the furnace are used at all the works without exception. In the present practice the blowers, which are of the ordinary fan type, are situated in the main engine house. Each works is provided with at least a duplicate installation and it is the common practice to run one fan by day and the other by night. In large works this arrangement involves the transmission of the air a long distance in order to reach the more remote furnaces.

Although the furnace of the dimensions described above has become the Iola standard, the Lanyon Zinc Co. experimented during 1901 with some furnaces of the same type, but with only 400 retorts, these being arranged in five rows of 40 each per side. Two furnaces of that size are installed end to end, with proper space between them, in a single house, giving thereby 800 retorts per house. The fact that the Lanyon Zinc Co. has been building some additional furnaces of the same dimensions indicates that the result of the first ones

were satisfactory. It is naturally to be expected that modifications in the number of retorts per furnace and their arrangement will be made from time to time, but there seems to be little probability that a further change from the Iola type of furnace as a type will have to be made so long as the supply of natural gas continues to be ample.

The standard Iola furnace distills per 24 hours per massive from 24,000 to 26,000 lb. of ore, with which is mixed 40 to 50% of coke and lean coal as reduction material. The furnace crew per massive consists of two firemen, who work 12-hour shifts, four chargers, six men in front of the car, four men behind the car and two condenser cleaners; on the night shift there are two metal drawers and one stuffer and metal piler. This arrangement obtains in all of the works of the district, with slight modifications; for example in some works there are only two firemen per two blocks. The maneuver is begun about 5 A.M. and is completed about 10:30 A.M.

*Ferraris Furnace.*—This is a new type of distillation furnace, invented by Erminio Ferraris, which has lately been introduced at the works of the Società di Monteponi, in Sardinia, where it has given very successful results. It is gas-fired and heat-recuperative, but has regenerative chambers for air alone, the gas being delivered already hot from the generator (which should be therefore set as near the furnace as is convenient) and being further preheated only by circulation through flues in the middle longitudinal wall, which divides the furnace into two separate combustion chambers. The movement of the burning gas through the combustion chambers is longitudinal, but the direction of the current is periodically reversed, wherefore there is no cold end. Beneath each combustion chamber there are two heat-recuperating chambers, filled with hollow brick, standard fire brick, or tiling, in such a way as to form numerous horizontal, parallel flues, which are divided into two groups by a horizontal partition, compelling the products of combustion entering at one end of the recuperative chamber from the corresponding end of the combustion chamber to traverse horizontally through the recuperative chamber, first through the upper division toward the middle of the furnace and thence backward through the lower division to the end, where communication is made with a longitudinal flue leading to a main flue which leads off from the middle of the furnace to the chimney. The gas from the producer, situated at one side of the furnace house, is delivered through a properly lined pipe to the center of the furnace overhead, whence it is directed, by changing the position of a valve, alternately to one end of the furnace or the other, passing through the flues in the middle wall. It enters the combustion chamber through ports below the lowest row of retorts, which ports are provided at intervals up to a line midway and transversely through the combustion chambers, so that the gas, instead of merely entering at the end, is distributed through the latter, thus insuring complete combustion of the gas by gradual admixture with air and a proper heat in the middle of the combustion chamber, which might otherwise average a little cooler than the ends. In the flue leading to the chimney there is a reversing valve to change the current of the products of combustion, which valve is connected with the gas valve over the furnace, so that the entire system will be operated together.

In operation the gas entering at one end of the furnace meets the hot air issuing from the recuperative chambers corresponding to that end. The burning gas passes horizontally toward the other end of the combustion chambers, enveloping the retorts on the way, and thence escapes into the recuperative chambers corresponding to that end, traveling horizontally through their flues and making a return pass before reaching the large flue leading to the chimney. In the meanwhile the air for the combustion of the gas is entering through the flues of the opposite pair of recuperators. At the end of the proper interval the direction of the currents of air and gas is reversed.

This furnace, which is designed on thoroughly scientific principles, has the important advantages of maintaining an equable temperature throughout a great length, and at the same time permitting the installation of a heat recuperative system of high efficiency. The appropriation of the entire available space under the combustion chambers to regenerative chambers for air alone simplifies the construction as compared with Siemens furnaces, in which heat is recuperated through the media of both gas and air. With regenerators for air alone there is no trouble from gas leakages and the hot brick of the flues is subjected only to the strongly cooling action of cold air. The gas, which is delivered to the furnace from above, arrives with much of the heat of the primary combustion in the producer, and is further heated during its circulation through the flues in the middle longitudinal wall; the heat that is acquired in the latter manner is no actual gain, however, inasmuch as it is abstracted by conduction and radiation from the combustion chambers to which it is immediately returned as caloric of the gas. The furnaces at Monteponi have 180 large retorts per massive and smelt from 6,000 to 7,000 kg. (13,228 to 15,432 lb.) of calcined ore per 24 hours.

*Neureuther Furnace.*—Charles F. Neureuther, of Peru, Ill., patented a modification of the Siemens regenerative Belgian distillation furnace, in which the air and gas are partially discharged half way up in the combustion chamber by means of vertical ducts and corresponding ports in the middle longitudinal wall. In the Siemens regenerative Belgian furnaces built heretofore in the United States the gas and air have been discharged under the lowest row of retorts; Neureuther states that with that method of heating the retorts of the upper rows have not been so highly heated as those of the lower rows, with the result that the ore charged into the upper retorts has required a longer time for distillation and the residues have been richer in zinc than they ought to be, and claims that by introducing the gas and air at different points in the height of the combustion chamber a more uniform temperature is obtained. He claims also that the capacity of the furnace is increased and that it is practicable to install at least one more row of retorts than in the older furnaces. The building of ducts in the middle of the longitudinal wall necessitates that the latter be made thicker at the bottom, on which account the retorts of the lowest two rows are made necessarily shorter than those of the upper rows.<sup>3</sup>

**NON-CORROSIVE RETORT LINING.**—An interesting development of 1901 was the practical application of the Sadtler retorts<sup>4</sup> at the works of the Midland

<sup>3</sup> United States Patent No. 666,390, Jan. 22, 1901.

<sup>4</sup> *Engineering and Mining Journal*, Sept. 29, 1900; *THE MINERAL INDUSTRY*, Vol. IX., p. 662.

Smelting Co., at Bruce, Kan., which were leased by the owners of the patents for the purpose of demonstration. Operations were begun June 10, since which time ore high in lead and iron from Colorado, together with some ore high in iron from the Joplin district, has been regularly smelted, apparently with successful results. I am informed that at least one other smelter in Kansas intends to give the Sadtler retorts a trial in 1902.

It is reported that a slight difficulty was experienced because of cracks some-

NEUREUTHER-SIEMENS REGENERATIVE FURNACE.

times occurring in the lining of these retorts, which would permit the slag to corrode through the retort and dripping down upon those of the lower ranks would corrode them from the outside. To obviate that difficulty the upper outside of the retorts has been coated in the same way as the inside, so that if a crack should occur in the lining of a retort in the upper ranks those situated below it will not suffer.

**QUALITY OF SPELTER.**—The quality of the spelter produced is a matter which

receives careful attention by the Kansas smelters, particularly in order to meet the requirements of the brass trade. Some of the smelters keep apart the first drawing of metal from the condensers and cast it in 50-lb. slabs which are sold under the names of "extra select," "brass special," or some other particular brand. Metal of that class contains but little more than 0.5% lead and is generally safely within the iron limit. The ordinary product of the Iola smelters is marketed in the form of slabs weighing from 65 to 67 lb., or roughly 30 slabs to the ton.

E. Herter, of Beuthen, Upper Silesia, patented an apparatus for separating lead from spelter simultaneously with the drawing of the latter from the condensers of the distillation furnace. The molten spelter is collected in a kettle lined with refractory material, which has a lip on one side and at the bottom an outlet hole fitted with a goose-neck or other suitable device for drawing off the lead settled from the spelter. The kettle is surrounded by a jacket, which is arranged with fire-bars at the bottom, and the annular space between the kettle and the jacket is kept filled with glowing coke. A cover is provided to close the annular division at the top. The whole apparatus is supported on trunnions at the end of a horizontal arm which is mounted on a movable carriage. The zinc is allowed to remain in the kettle at any desired temperature for as long a time as may be necessary to permit separation of the lead.<sup>5</sup>

MISCELLANEOUS PROPOSALS.—Following are some of the miscellaneous proposals for the recovery of zinc from its ores, which have been referred to in the literature of the year.

*Reduction of Blende by Calcium Carbide.*—L. M. Bullier patented a process for the metallurgical treatment of sulphide ores by smelting with calcium carbide. The ore, with or without a preliminary roasting, is fused at a clear red heat with granulated calcium carbide and a suitable flux for about one hour, by which means copper and certain other metals may be separated in what is claimed to be an entirely novel manner. In treating the sulphides of volatile metals a closed apparatus is used.<sup>6</sup>

*Electric Smelting.*—Casaretti and Bertani patented a process for the production of zinc by smelting in an electric furnace, which is being worked by the Società Elettro-metallurgica Lombarda. It is claimed that 1 kg. zinc is produced per 2 H.P. hours, the quantity of coal consumed in each furnace being 15 kg. per 100 kg. of ore.<sup>7</sup>

RECOVERY OF ZINC FROM WASTE PRODUCTS.—J. Richards lately described some methods used practically for the recovery of zinc from galvanized iron scrap, and other waste material, in connection with the recovery of tin from tin-plate scrap, which are of much interest.<sup>8</sup>

*Tin and Galvanized Iron Scrap.*—The method employed for the treatment of this material consisted in immersing the tin-plate scrap in hydrochloric acid until the tin was dissolved, followed by an immersion in water, then in water with a little lime, then again in water, and finally for a moment in a solution of copper sulphate. The vats containing the various solutions were arranged in

<sup>5</sup> British Patent No. 8,175, April 20, 1901.

<sup>6</sup> British Patent No. 9,048, of 1900.

<sup>7</sup> L. Belloc, *Elettricità*, Milan, XIX., 598; *Science Abstracts*, 1901, IV., 1, 74.

<sup>8</sup> *Journal of the Franklin Institute*, CLI., 445-455; CLII., 59-68.

a semicircle, commanded by a central crane; they were 6 ft. in diameter, 6 ft. in depth, and were sunk in the ground. The scrap was packed in a wooden cage, holding 200 lb., which was handled with the aid of the crane. The object of dipping the cleaned scrap in the solution of copper sulphate was to deposit upon it a thin coating of copper in order to protect the iron from rust, until after consolidation under a drop-press it could be reheated and forged into blooms. The tin was recovered from the chloride solution by dipping galvanized iron scrap in it, whereby metallic tin was precipitated by the zinc dissolved from the iron, zinc chloride being formed by the reaction. The precipitated tin was then collected and remelted, and the zinc chloride was sold for use as a disinfectant. About 600 lb. of tin were recovered from 10 tons of scrap. The cleansed iron sold for \$10 per ton.

*Waste Products from Galvanizing.*—Sal ammoniac skimmings from the surface of the zinc bath used in galvanizing, which consist chiefly of zinc oxide dissolved in ammonium chloride and double chloride of zinc and ammonium, were leached with hot water and steam, whereby the chlorides were dissolved. They could be recovered for further use as galvanizing flux by boiling down the solutions and crystallizing them out. The residuum from the lixiviation, consisting of zinc oxide, dirt and shots of zinc, was tumbled in a revolving barrel whereby the shots of metal were cleaned so that they could be remelted on the top of a pot of molten zinc. The zinc oxide which became crushed to a powder was marketable at \$30 per ton with manufacturers of zinc paint. The average yield of such skimmings from galvanizing was 20% spelter, 30% ammonium and zinc chlorides, 35% zinc oxide and 15% iron scale and dirt.

*Zinc Dross.*—The zinc-iron alloy, known as zinc dross, which accumulates at the bottom of the galvanizing pots, was treated by melting and introducing into the molten metal (below the surface thereof) a mixture of sulphur, potatoes and leather scrap. After about 15 minutes, action having been completed, a little aluminum was introduced in order to break up dissolved oxides. After permitting to stand for a short time, pure metal could be ladled off, most of the impurities of the dross remaining at the bottom of the pot. A sample of 40 carloads of spelter obtained in this way assayed 98.35% Zn, 1.5 Pb and 0.15% Fe. Spelter refined a second time by the same process contained from 99 to 99.75% Zn, the only impurity being lead. A third refining failed to raise the percentage of zinc higher than 99.85. Scrap zinc could be treated in the same way. The aluminum was most successfully introduced in the form of an alloy containing 98% Zn and 2% Al.

*Zinky Lead.*—The zinky lead which collects at the bottom of galvanizing baths was treated by remelting in a wide pot at a temperature only just above the melting point of lead. An iron ring, 2 ft. in diameter and 6 in. in depth, was placed on the surface of the metal, and the zinc was skimmed off within the ring as fast as it rose to the top in a pasty condition. The lead still contained about 2% Zn after this treatment; a further elimination of the zinc would be of course a simple matter by the ordinary refining process, which is employed in connection with the desilverization of lead. The impure lead found a ready market, however, for the manufacture of weights, counterbalances and for use as ballast, etc.

**ZINC OXIDE.**—One of the most important recent developments in the American zinc industry has been the remarkable increase in the production of zinc oxide. It is said that this has been partly absorbed by an increased consumption in the rubber trade, zinc oxide being an important ingredient in the compounding of rubber; it has partly been exported, there being a growing foreign trade in the American product; but notwithstanding those demands it must have gained great headway in the domestic paint trade in competition with the other white pigments, especially white lead. The merits of zinc white as a pigment were summarized by Maximilian Toch in a paper recently read before the New York Section of the Society of Chemical Industry.<sup>9</sup> He stated that the consumption of white lead is decreasing and that it should not be used alone. The specifications of the United States Lighthouse Department demand 75% of zinc oxide and 25% of white lead. Zinc white mixes well with other pigments, particularly with white lead. Zinc oxide made directly from ore is more durable than that made by burning spelter, and on a very large surface the difference in whiteness is soon apparent. Zinc oxide as the drying progresses becomes very hard and brittle, this being more the case with oxide made from spelter than with that made directly from ore. This is overcome by treating the linseed oil with 0.33% of litharge before mixing with the zinc white, a flexible drying paint being thus produced, which is essential in the manufacture of oilcloth. Zinc oxide is not affected by hydrogen sulphide, which gives it a superior advantage for the painting of the interiors of buildings. It is less absorbent than other paints, and can be washed. On outside walls it withstands well the action of the atmosphere when used to the extent of 50% mixed with white lead and barium sulphate.

A new plant for the manufacture of zinc white was erected at Joplin, Mo., in 1901 by the Renfrow Paint Co. The raw material that is to be employed is a zinc carbonate, assaying about 37% Zn, which is obtained from what is supposed to be a large deposit at West Plains, Mo.

W. B. Middleton patented a special furnace for the direct production of zinc white from ore. This furnace is of the reverberatory type, but is without a fire-bridge and has a fire-box about 3 ft. deep. The fire-box is filled with fuel, and a charge of roasted blende, or calamine, is put on the hearth. When it becomes hot it is raked off the hearth on to the top of the incandescent fuel, and a fresh charge is put into the furnace, more fuel being thrown into the fire-box at the same time. As soon as the hot ore reaches the fuel, zinc fumes are evolved and travel over the hearth into a suitable condensing chamber. The fire-bars of the furnace are carried loosely on notched bearers, beyond which their ends project, so that they can be turned by means of levers in order to break up and remove the clinker.<sup>10</sup>

**ELECTROGALVANIZING.**—The use of electrogalvanizing for the production of boiler tubes and for the coating of torpedo plates and torpedo-boat fitting has been increased by the recent construction of an electrogalvanizing plant for Messrs. John Cockerill & Co., of Seraing, near Antwerp, Belgium. The con-

<sup>9</sup> *Journal of the Society of Chemical Industry*, Jan. 31, 1902, p. 102.

<sup>10</sup> British Patent No. 12,274, June 15, 1901.

struction and working of the plant is similar to the one built in 1900 for the German Shipbuilding & Engineering Co., at Tegel, near Berlin, a description of which appeared in *THE MINERAL INDUSTRY*, Vol. IX., pp. 683-685.

**TREATMENT OF MIXED SULPHIDE ORES.**—The mixed sulphide ores of Leadville, Colo., have been treated on a large scale by careful separation of their minerals with the aid of Wilfley and similar tables. The galena concentrate finds a ready market with the lead smelters and the blende concentrate has been of such a character that the zinc smelters would take it at a low price, generally \$6@\$7 per 2,000 lb. f. o. b. Leadville. The larger part of the Leadville product, which probably averages about 45% Zn, 6% Pb and 10% Fe, has been exported to Europe, via Galveston, the freight from Leadville to Swansea and Antwerp being about \$9.50 per 2,000 lb. In 1900 the total production of zinc ore in Colorado, according to H. A. Lee, commissioner of mines, was 77,984 tons, averaging 42% Zn; this doubtless included all the ore that was used for the manufacture of zinc white, and zinc-lead pigment, as well as for spelter. In 1901, Leadville produced 23,261 tons of zinc ore. In addition to Leadville, shipments of zinc ore are made from Silver Plume, Montezuma, Creede, Rico, and elsewhere in Colorado.

The fact that Colorado blende contains iron in its composition makes it susceptible to the intense magnetic influence of the Wetherill machines and enables it to be separated from the intermixed galena and pyrite, which are both absolutely non-magnetic. Experiments have demonstrated that this is a process which will be commercially successful, and the Colorado Zinc Ore Co. and the New Jersey Zinc Co. have been lately erecting magnetic separating plants at Denver and Cañon City respectively, which ought to be in operation in 1902. The indications point toward the production of an ore of about the same percentage of iron as that which the present concentrating mills are furnishing, but several units higher in zinc and lower in lead. A magnetic separating plant is said to be already in operation at Rico.

The treatment of mixed sulphide ores by the Sadtler process of distillation has been referred to previously in this review. Some of the new proposals of a hydro-metallurgical and electro-metallurgical nature are summarized in the following paragraphs.

**Bechi.**—Guy de Bechi, of Paris, France, patented the roasting of zinkiferous sulphide ores with admixture of from 15 to 30% of silica, whereby it is claimed the zinc is rendered more completely soluble in acids than when the ore is roasted without such admixture.<sup>11</sup>

**Clancy & Marsland.**—J. C. Clancy and L. W. Marsland, both of Sydney, N. S. W., are the inventors of a process which is being exploited by the Clancy-Marsland Sulphide Process Co., Ltd., of Sydney, and has been tried experimentally at that place. The fundamental feature of the process, which is described with numerous modifications, is the admixture with the ore of lead sulphate in molecular proportion and heating, whereby it is claimed that the ore is decomposed in a manner analogous to that which takes place in the roast-reaction method of smelting galena. It is claimed that in this way the zinc is rendered

<sup>11</sup> British Patent No. 985, Jan. 16, 1900; *Journal of the Society of Chemical Industry*, Jan. 31, 1901, p. 47.

completely soluble in sulphuric acid, while the desulphurization of the ore is completed in so short a time as 30 minutes. The reaction is effected in a reverberatory or muffle furnace, either below or above the temperature at which lead will be volatilized. In the former case the desulphurized ore is treated with sulphuric acid in order to obtain soluble zinc sulphate and insoluble lead sulphate; in the latter, the gas from the furnace, laden with zinc-lead fume, is passed into dilute sulphuric acid; in either case the results finally accomplished are the same. The lead is obtained as sulphate, of which the necessary proportion for the decomposition of more ore is reserved, while the remainder is smelted for metal. The zinc is obtained as a solution of its sulphate, which is evaporated to dryness and heated to the temperature of decomposition, in order to obtain zinc oxide as the final product. The sulphurous and sulphuric gases evolved during different stages of the process are converted into sulphuric acid. The process in its numerous modifications is described in a pamphlet published by the company which is promoting it, and in numerous patent specifications.<sup>12</sup>

*Davis.*—G. E. Davis and A. R. Davis, of Manchester, England, patented a process for the treatment of mixed sulphide ores by digestion with dilute nitric acid, a preliminary roasting being unnecessary, since nitric acid decomposes most sulphides. Zinc, lead and iron go into solution as nitrates, and all but the zinc can be precipitated by addition of zinc oxide, which if properly regulated will enable a fractional separation of the metals to be made and the lead to be recovered separately. Lead is precipitated from the mixed solution of zinc and lead nitrates by adding zinc oxide and passing in carbonic acid gas, whereby lead carbonate is thrown down, zinc replacing lead in the solution. It is preferred to conduct the process in two stages, less than the theoretical quantity of zinc oxide, mixed with the lead precipitate of a previous second stage operation, being used in the first; in the second stage an excess of zinc oxide is employed.<sup>13</sup> The purified solution of zinc nitrate is then evaporated to about 1.5 sp. gr. and furnaceed for the production of zinc oxide and gaseous nitrogen compounds. The latter together with the nitrous fumes from the original treatment of the raw ore are recovered as nitric acid, available for attacking a fresh lot of ore. The residue from the digestion with nitric acid contains silica, sulphur and lead sulphate, together with gold and silver. The nitric acid used for attacking the ore may be diluted with weak zinc nitrate solution so as to obtain a stronger solution for the ultimate evaporation.<sup>14</sup>

The Messrs. Davis also proposed to treat sulphide ore by digestion with hydrochloric acid, saturating any free acid in the liquor therefrom with zinc oxide, oxidizing any iron therein to the ferric state, precipitating ferric hydroxide by means of zinc oxide, and then precipitating silver from the solution as iodide by the Claudet process. After removal of the lead by means of zinc oxide and carbonic acid gas as described in another patent<sup>15</sup> the residual solution of zinc chloride is to be concentrated for recovery of that salt, or the zinc is to be pre-

<sup>12</sup> Among others, British Patents Nos. 4,039 and 9,503, of 1901.

<sup>13</sup> British Patent No. 253, Jan. 4, 1900.

<sup>14</sup> British Patent No. 710, Jan. 11, 1900.

precipitated therefrom as oxide. The residuum from the original lixiviation with hydrochloric acid is to be treated with hot water to dissolve out the lead chloride therein, which may then be recovered as such, or as carbonate. The silver may be extracted by means of ammonium or sodium thiosulphate, and the residue then remaining may be roasted to convert undecomposed zinc sulphide into oxide for use in saturating the free acid in the original solution from the first ore treatment. In digesting the ore with hydrochloric acid, hydrogen sulphide is evolved which may be burned to sulphurous anhydride for the manufacture of sulphuric acid or from which sulphur may be recovered by the Claus method. A modification of this process consists in the treatment of only three-fourths of the ore with hydrochloric acid, the lead sulphide being more readily attacked than the zinc, and of roasting the remaining fourth into a crude zinc oxide which may be used for the purpose of saturating the free acid as before mentioned.<sup>15</sup>

*Ellershausen.*—F. Ellershausen took out a further patent<sup>16</sup> on the process which has been experimented with upon a large scale at Angoulême in France and was referred to in *THE MINERAL INDUSTRY*, Vol. IX., p. 688.

*Ferraris.*—Erminio Ferraris patented a process for the treatment of mixed sulphide ore, wherein the ore is heated with concentrated sulphuric acid in a furnace, by which operation there are produced metallic sulphates, sulphurous acid, water and sulphur. The sulphur is burned and the whole of the sulphurous acid is then converted into sulphuric acid. The ore withdrawn from the furnace is leached with water to dissolve the soluble sulphates. From the solution, the copper and the iron present as ferric sulphate are precipitated by means of zinc oxide. The iron present as ferrous sulphate is then precipitated by means of zinc oxide and compressed air injected into the hot solution. Zinc sulphate is to be recovered from the purified solution by boiling down. In order to obtain zinc oxide, for the recovery of metallic zinc, it is proposed to heat the zinc sulphate with admixture of carbon.<sup>17</sup>

*Ganelin.*—Solomon Ganelin, of Berlin, Germany, proposed to introduce zinc-lead compounds, in the form of oxides, into molten zinc chloride and electrolyze for recovery of the metals.<sup>18</sup>

*Kellner.*—Carl Kellner, of Vienna, Austria, patented the process of converting the zinc compounds of roasted ore into sulphites, changing to sulphates by a suitable oxidizing agent, and adding to the solution an alkaline earth chloride, thereby precipitating the corresponding sulphate and affording a solution of zinc chloride from which the metal may be recovered.<sup>19</sup>

*Swinburne and Ashcroft.*—The so-called Phoenix process, invented by James Swinburne and Edgar A. Ashcroft, was described by the latter in a paper read before the Institution of Mining and Metallurgy, London, June 19, 1901. It was stated that although the process has not yet been applied on a commercial scale, considerable quantities of ore have been treated by it and many tons of zinc and lead have been extracted. This process has previously been described in *THE*

<sup>15</sup> British Patent No. 2,089, Feb. 1, 1900.

MINERAL INDUSTRY, especially Vol. IX., p. 692. The reactions involved in it are so novel and the problem of the electrolysis of molten zinc chloride has been worked out in so interesting a manner that it appears to be worth while to present a rather extended abstract of Mr. Ashcroft's paper.

As described by Mr. Ashcroft the principles which characterize the process are as follows:—

I. Displacement of sulphur (or other elements) from combination with metals in the ore, by means of chlorine gas in the dry way.

II. Substitution of one metal for another in a mixture of fused chlorides by precipitation with a metal, or by the fractional electrolysis of the mixed chlorides in a fused state.

III. Separation of siliceous gangue from the final metallic chloride by settling and decantation, and washing the residue with water (or alternatively by distillation of the chloride from the residue).

IV. Purifying the chloride, boiling down the wash solutions, if any, and preparing the chloride for electrolysis.

V. Electrolytic decomposition of the final chloride for the recovery of its metal and chlorine, the latter being recovered and collected under a suitable pressure.

The decomposition of a sulphide ore by chlorine is represented by the following equation:—

If the ore be an oxide, instead of a sulphide, the reaction is expressed as follows:—

These reactions are claimed by the inventors to be an original discovery. It has heretofore been supposed that when a metallic sulphide was treated with chlorine gas, both the corresponding metallic chloride and sulphur monochloride would be formed. This would occasion large losses of chlorine and involve other difficulties which would render the process economically impracticable. Messrs. Swinburne and Ashcroft claim to have proved, however, that the formation of sulphur monochloride takes place only at low temperatures, and instead of that product being a necessary result of the reaction between chlorine gas and the metallic sulphide, liquid sulphur monochloride can be employed for the decomposition of such sulphides, in which case both the sulphur of the ore and that of the sulphur monochloride is recovered; in fact sulphur monochloride is only formed by the action of excess of chlorine on the liberated sulphur at low temperatures. The critical temperature at which sulphur monochloride ceases to form when metallic sulphides are treated with chlorine gas is approximately 600°C., which is also approximately the lowest temperature at which chlorine gas ceases to attack actively the sulphides. It attacks them slowly, however, at much lower temperatures.

The method adopted by Messrs. Swinburne and Ashcroft for decomposing the ore is to employ a vessel of large size, called a converter, into which is introduced, at a suitable temperature, an emulsion of the sulphides under treatment with fused zinc chloride. Chlorine gas is then injected at the bottom and ore is fed in

at the top, the resulting sulphur, which is vaporized at any temperature above 450°C., being carried away into a condensing chamber or flue and there collected. Decomposition is rapid and complete, and the heat set free in the reaction maintains the proper temperature. The addition of ore to the converter and the blowing in of chlorine gas is continued until the apparatus is full of fused chlorides in the molten state, in which the siliceous gangue remains suspended. The greater part of the contents of the converter is then tapped off through a hole, or decanted by tipping the converter; that which remains holds sufficient heat to enable the process to be resumed by blowing in more gas and putting in more ore. The process is completely under control, and inasmuch as the reaction is strongly exothermic the heat can be regulated, and maintained at the most suitable temperature, by altering the rate of working. It is possible by forcing the latter to distil off the chlorides from the converter. It is unnecessary to crush the ore very fine, comparatively large grains being readily acted upon. An apparatus of small size puts through an astonishing quantity of ore and works with great facility. The sulphur comes off as vapor which is easily condensed, and nothing escapes from the condensing chamber except such small quantities of impurities as may have been mixed with the chlorine gas in the first instance, and any sulphurous anhydride gas corresponding to sulphur burned by air accidentally admitted. The fused chlorides run from the converter more freely than the most fluid of slags.

In the treatment of 1,000 kg. of ore, assaying 29% Pb, 26% Zn, 21% S, 5% Fe, 2% Mn, 17% gangue, and 19 oz. silver per ton, there was consumed 470 kg. of chlorine gas. The experiment lasted 12 hours. The average temperature was 650°C. Four pours were made. The condensed sulphur weighed 100 kg.; the remainder of the sulphur in the ore was burned to sulphurous anhydride and escaped. The condensed sulphur was readily purified, associated chlorides being recovered by washing with water. If a little acid be present in the wash water, the sulphur assumes the brilliant yellow color of pure brimstone. All of the gangue and 92% of the chlorides remained in the converter; 8% of the chlorides (consisting mainly of iron and zinc chlorides) was carried away with escaping sulphur vapor and was found in the condenser. The quantity of fused chlorides obtained was 1,260 kg., which assayed as follows: 23% Pb, 21% Zn, 4% Fe, 1.5% Mn, 37% Cl, 13.5% gangue, and 15.5 oz. silver per ton. This represented a conversion of the entire metallic contents of the ore into chlorides, except the iron and manganese contents of the siliceous gangue which remained as silicates. The fused chlorides were free from sulphur.

The silver contained in the fused chlorides (and similarly gold if it be present) can be completely extracted by agitating the mixture with metallic lead, whereby rich bullion is produced which contains all the precious metals present. The reaction is said to be remarkably complete. If the chlorides contain antimony or copper, either lead or zinc may be used for their extraction. The copper is most easily obtained in alloy with excess of zinc as brass, owing to its high melting point. Metallic lead is extracted from the chlorides by means of metallic zinc, which operation consumes a considerable quantity of zinc, producing the equivalent of zinc chloride. The lead may be obtained quite free from zinc by

performing the operation in two stages at a low temperature (approximately 450°C.). Iron and manganese are removed from the converter mixture as oxides, either before or after the chlorides have been separated from the siliceous gangue, which is done by settling and decantation, by solution of the residual chlorides in water, and finally boiling down the pure solution in a suitable apparatus. After the recovery of the silver and lead by means of metallic zinc as described above, the only foreign element in a mixture of chlorides of the character shown by the analysis previously quoted, which would interfere with the electrolysis of zinc chloride is iron, and that metal is readily oxidized to ferric oxide in the converter by the application of a blast of air at a certain stage of the converter process. The suspended ferric oxide is afterward removed with the gangue matter. Manganese is quickly removed as dioxide by the same means, but inasmuch as it does not interfere in the electrolysis of fused zinc chloride its complete removal is not important, and it is eliminated only to prevent undue accumulation in cyclic working.

The following reactions are supposed to occur in removing iron and manganese:—

In order to separate the heavy siliceous matter and the iron and manganese oxides from the zinc chloride, the latter is allowed to stand long enough to permit the impurities to settle, after which various quantities of pure zinc chloride can be decanted off. The residue may be distilled in fire-clay retorts, and the zinc chloride (which volatilizes at 720°C.) be collected, but a more convenient practice is thought to be washing the residue with water and boiling down the solution of zinc chloride until fused. The latter is the method which has been adopted in the experimental work.

The solutions are boiled down first in lead lined vessels, and finally in enameled iron pans, or in tank furnaces in which the solution is heated from above. In the boiling down process the chloride behaves much like caustic soda, frothing a little at the end and then settling down to tranquil fusion. Fused zinc chloride, when free from lead and other chlorides and water, is readily handled and dealt with in iron pots and with iron tools, which it does not attack. At temperatures below 400°C. it is fluid and does not fume in the air. The dehydration of the zinc chloride and elimination of the last traces of iron, lead and other impurities, which would contaminate the spelter or interfere with the electro-deposition, is effected by means of a short preliminary electrolysis with a cheap form of carbon anode, which is destroyed by the oxygen liberated. This preliminary treatment is carried out in a special form of vat arranged for easy removal of carbons and easy cleaning out. It affords a zinc chloride which is free from hydrogen, iron, and lead, and can be decomposed by electrolysis to the best advantage. The power consumed in this preliminary process need not exceed 10% of that required for the final decomposition of the zinc chloride. The vats are left open to the air inasmuch as no chlorine is evolved until the treatment is complete.

The final electrolysis of the zinc chloride is effected in a circular steel tank, 6 ft. in diameter, lined with 18 in. of ordinary Stourbridge fire brick, the inner courses of which are set in a special cement. The cathode in each tank is molten zinc weighing about one ton. Connection with it is made by means of a heavy steel block buried in the brick work and provided with five screwed, copper, tubular rods through which the current enters from the outside and through which free circulation of air can take place to prevent overheating. The anode consists of a removable cast-iron plate, lined on the under side with a special cement, from which hang 120 rods of hard carbon, 2.25 in. in diameter, in such a way that they are immersed about 6 in. in the electrolyte. It will be observed that zinc chloride is maintained in a molten condition by internal heating by the current. A vat of the above dimensions takes a current of from 3,000 to 4,000 amperes with from 4 to 4.5 volts at the terminals and produces nearly a ton of zinc per week.

The current efficiency of the process, after the preliminary electrolysis, is about 95%, which allows for all leakage, etc. The pressure efficiency is, however, much lower. The theoretical electromotive force required for the decomposition for zinc chloride is 2.2 volts. The normal working electromotive force is about double that. By especially coating the vat of the dimensions specified above and conserving the heat, it is possible to work at 2,500 amperes, at which low current density, when the same gap is preserved between the carbons and the zinc, the pressure will fall to 3.5 volts. Ashcroft considers that with large units (say 10,000 amperes) a working pressure of three volts or even less might be obtained, inasmuch as the heat is more easily conserved in a large than in a small apparatus. In the latter case the watt efficiency would be 69.7%; or 60% after making allowance for the preliminary electrolysis. In the experimental work so far an electromotive force of four volts has been employed and the watt efficiency has been only 40%.

The molten zinc is tapped directly into molds, by removing a carbon plug, and fresh zinc chloride is poured into the vat by means of a crane and a tipping-ladle. The labor required for attendance to the vats is comparatively small, the difficulties accompanying the collection of the zinc in solid form and remelting it when a solution is decomposed being entirely obviated. The brick lining of the vats is not attacked; at least no injury was manifest after nine months' working. The carbon anodes last six months at least; when the preliminary treatment is properly carried out the action of pure zinc chloride on them appears to be *nil*, and since the anodes have seldom to be removed accidental breakages are not heavy. The quality of the spelter produced depends almost entirely upon the care taken in purifying the chloride. It appears to be not at all difficult to produce a product assaying 99.83% Zn, 0.15% Pb and 0.02% Fe.

The chlorine gas escaping from the electrolytic vats is drawn off into a holder by means of a small ebonite coated fan and motor. The vats are carefully closed to prevent as much as possible any dilution of the chlorine by air. The necessary holes through the cover are sealed by means of an earthenware tube, dipping into the molten chloride. The temperature of working is between 425 and 525°C., and should not vary beyond those limits for the best results. It is

found advantageous to the electrical conductivity to have sodium chloride, calcium chloride, etc., in admixture with the zinc chloride to the extent that the electrolyte will assay not more than 28% Zn, against 48.5% Zn for pure zinc chloride. These foreign chlorides are not decomposed in the presence of zinc chloride, and therefore do not require renewal.

The chlorine gas drawn from the holder is dried by causing it to pass through a tower packed with zinc chloride. For convenience in storage it is then liquefied. The handling of this gas was at first a troublesome problem, but it is claimed that satisfactory apparatus has now been devised. The gas is blown into the converter under a pressure of 50 lb. per sq. in.

Mr. Ashcroft estimates that an ore assaying 20% Pb, 20% Zn, 8% Fe + Mn, 18% S and 34% siliceous gangue, together with 12 oz. silver per ton (1,000 kg.) will yield 100% of its lead, zinc and silver and 55.5% of its sulphur. He estimates the cost of treatment per 1,000 kg. at £1 10s., not including power, but including repairs and renewals, administration and general expense, and interest and depreciation (reckoned at 10% of cost of plant); also replacement of zinc chloride lost in the process, which is estimated at 5%. With power costing £4 per E.H.P. per annum (a rate that is obtainable in the utilization of certain water powers) the cost per ton of ore would be 13s.; making the total cost of treatment £2 3s. = \$10.50 per 1,000 kg. = \$9.50 per 2,000 lb. A plant for the application of this process upon a manufacturing scale is to be erected at Weston Point, England.

*Twyman.*—T. Twyman, of Moortown, England, proposed to mix finely ground ore with a suitable proportion of zinc chloride and heat to just about, or a little below, visible red heat, with exclusion of air. Lead sulphide is thus converted into chloride, which can be leached from the ore, leaving all the zinc behind as sulphide. The residuum containing the zinc sulphide may be treated as a zinc ore in the ordinary manner; or it may be roasted to sulphate and oxide, and the sulphate having been dissolved out may be employed for precipitation of the lead from the chloride solution as sulphate, thus regenerating zinc chloride. As an alternative the mixture of sulphate and oxide of zinc may be used to precipitate a mixture of sulphate and oxide of lead.<sup>20</sup>

*Worsey.*—J. W. Worsey, of St. Helens, England, patented a process wherein mixed sulphide ore is roasted so as to contain between 8 and 16% S. The ore is then ground and mixed with about 2% of sodium nitrate and sufficient dilute sulphuric acid to combine with all the zinc present. The mixture is then heated in a water-tight vessel whence the fumes are carried off to a sulphuric acid chamber, more nitrate being added if necessary. The residue is roasted in a muffle furnace, with or without an oxidizing agent, and the soluble sulphates are then dissolved out with water containing sodium sulphate. The clear solution is precipitated with milk of lime, and the precipitate is heated in the presence of air in a furnace, the zinc being volatilized and collected in the form of oxide. The oxidizing agent to be added to the charge in the furnace during the roasting, in order to oxidize ferrous iron, is sodium nitrate, with or without lime.<sup>21</sup>

<sup>20</sup> British Patent No. 14,968, Aug. 22, 1900.

<sup>21</sup> British Patent No. 3,668, Feb. 24, 1900; United States Patent No. 678,210, July 9, 1901.

**ANALYTICAL METHODS.**—Some of the new analytical methods for the determination of zinc and cadmium, that were described in 1901, are briefly abstracted follows:—

**Ferrocyanide Method.**—Dr. A. C. Langmuir stated at a meeting of the New York Section of the American Chemical Society, March 8, 1901, that he had found uranium acetate to be an unreliable indicator in the presence of small quantities of hydrochloric acid, a 3 or 4% solution of uranium nitrate being preferable. This recommendation is supported by the experience of other chemists.<sup>22</sup>

**Precipitation of Zinc Hydroxide by means of Dimethylamine.**—W. Herz has shown that the reaction between ammonia and zinc sulphate is incomplete, owing to the fact that the basicity of the ammonia is weakened by formation of ammonium sulphate. The stronger bases, methylamine and dimethylamine, precipitate the whole of the zinc in the form of hydroxide. The precipitated zinc hydroxide is soluble in excess of methylamine, but not so in the case of dimethylamine. The latter can be used therefore for the determination of zinc, and can afterward be recovered from the filtrate by making the latter alkaline and stilling.<sup>23</sup>

**Titration with Sodium Thiosulphate.**—P. Knaps described a method for the determination of zinc by means of iodine solution. Zinc sulphide, in the acetic acid solution in which it is ordinarily precipitated, is converted by iodine into zinc iodide and sulphur. If, however, more than 0.05 g. of zinc sulphide to 10 c.c. of water be present, the separated sulphur protects particles of it from the action of the iodine. This can be prevented by forming a precipitate, such as barium sulphate, in the liquid prior to the introduction of the hydrogen sulphide. Thus, from 10 to 20 c.c. of a solution of 150 g. of barium chloride in a liter, and the same quantity of sodium sulphate solution (200 g. per liter), are introduced, the zinc precipitated, and the excess of hydrogen sulphide removed by boiling. An excess of standard iodine solution is then added, the liquid is shaken for one or two minutes, and the excess of iodine is titrated with standard sodium thiosulphate solution. Ammonium salts do not interfere, and the results are accurate even in the presence of considerable quantities of manganese salts.<sup>24</sup>

**Determination of Zinc as Phosphate.**—P. H. Walker described a method for the volumetric determination of zinc which is a modification of that devised by Stolba for the determination of magnesium. To the zinc solution, which should contain ammonium chloride, a large excess of ammonia is added, followed by a large excess of sodium phosphate solution. Hydrochloric acid is then gradually added until, after stirring, the solution remains milky. It should then be heated to about 75°C., and the gradual addition of acid continued, with constant stirring, until nearly complete neutralization is attained. By this means the precipitate becomes crystalline; after standing five minutes it should be filtered off and washed with cold water until the washings show only a faint

<sup>22</sup> Vide THE MINERAL INDUSTRY, IX., 675.

<sup>23</sup> Zeitschrift fuer Anorganische Chemie, XXVI., pp. 90-93; Chemische Centralblatt, I., vii., 868.

<sup>24</sup> Chemiker Zeitung, XXV., 539-540.

trace of chlorine. The filter paper and precipitate are then returned to the beaker in which the precipitation was carried out, an excess of standard acid is added, and the exact point of neutrality is determined by means of standard alkali, using methyl orange as indicator. The reaction which takes place is represented by the following equation:—

Calculation from the above equation shows that 1 c.c. of normal acid corresponds with 32.7 mg. of zinc.

The method gives good results. Since the zinc ammonium phosphate is not precipitated in presence of a large excess of ammonia, any magnesium present, which will be precipitated, may be removed by filtration, and the filtrate neutralized to throw down the zinc. Fairly good results are obtained by this method also in the presence of iron, calcium, and magnesium, but any manganese must be previously separated, best by means of nitric acid and potassium chlorate.<sup>23</sup>

*Analysis of Spelter.*—The following short method was described by Dr. A. C. Langmuir, in a paper read before the New York Section of the American Chemical Society, March 8, 1901: Cover the sample with water, add a few drops of platinum chloride, and then sufficient sulphuric acid to start a moderate rate of solution. After the zinc has dissolved, filter off the lead, dissolve the latter on the filter with nitric acid and convert to sulphate as usual. The solution of zinc may then be at once titrated for iron with permanganate solution, after which cadmium may be precipitated with hydrogen sulphide.

*Estimation of Cadmium.*—E. H. Miller and R. W. Page have recently investigated several methods for the quantitative determination of cadmium.<sup>24</sup> They found the electrolytic method to be very accurate if a large excess of potassium cyanide and the presence of other salts be avoided. The carbonate method is the most troublesome and the least accurate. A very accurate method is the precipitation of cadmium from a neutral solution (cold) by a large excess of di-ammonium hydrogen phosphate and either weighing the precipitate as  $\text{CdNH}_4\text{PO}_4 \cdot \text{H}_2\text{O}$  on a tared filter (after drying at 100 to 103°C.), or dissolving it in dilute nitric acid and igniting to pyrophosphate.

#### THE CERMAK-SPIREK FURNACE FOR CALCINING AND ROASTING ZINC ORES.

BY VINCENT SPIREK.

THIS furnace was built for the Crown Spelter Co., Ponte di Noss, Bergamo, Italy, and has been in successful operation since July, 1901. The furnace is of the Cermak-Spirek type having a capacity of from 10 to 12 tons per day. A thorough preheating of the flames is effected in the lower part, the flames entering by two openings (shown in Fig. 1) which are independent and can be controlled to suit the character of the material to be roasted, whether smithsonite or zinc blende. As will be seen from the drawings, the furnace is square in outline and rests upon bedplates supported by T rails. In the bedplates are gates through which the roasted ore may be discharged by means of the device

<sup>23</sup> *Journal of the American Chemical Society*, XXIII., vii., 468-470.

<sup>24</sup> *School of Mines Quarterly*, 1901, XXII., iv., 301-308.

shown in Figs. 2 and 3. The interior of the furnace is filled with sets of transverse tiles of V shape, the apex upward, and staggered so that the apex of each tile comes opposite the space between the edges of the two tiles in the layer next above. The ore rests upon the sides of these tiles, and gradually works down as the roasted material is withdrawn. The flames pass from the hearth into the channel *L* III., Fig. 2, which is also connected with the air entrances,

Fig. 1.—Horizontal Sections, O-R, Q-R, S-T.

#### THE CERMAK-SPIREK FURNACE FOR CALCINING AND ROASTING ZINC ORES.

and from this point they are drawn longitudinally through the tile passages back and forth from tier to tier until they reach the outlet at the top of the furnace. For the calcining process a high temperature (1,100°C.) and a thorough roast are necessary, hence the full area of the openings are taken up by the flames. By providing two separate entrances for the flames it is possible to effect a thorough roasting of mixed ores that are to undergo a subsequent magnetic concentration by using the upper flame alone. The required amount

of fine coal can then be introduced by means of long shovels and the material be brought to the lower part of the furnace where after closing the air entrance it is subjected to the reducing action of carbon monoxide by which the ferric oxide formed during the first operation is reduced to magnetic oxide. During

Fig. 2.—Vertical Sections, G-H, I-L.

#### THE CERMAK-SPIREK FURNACE FOR CALCINING AND ROASTING ZINC ORES.

the second or reducing stage the upper flame entrance should be closed. The gases pass through the four channels and may be used to heat the descending ore. At Ponte di Nossa this is effected by conducting the gases through horizontal covered channels before entering the chimney. The results of a four-

months' run of this furnace have been published by Ernesto Zay and Arthur T. Francis in the *Resoconti della Associazione Mineraria Sarda*, 1901, Vol. VI. The amount of smithsonite treated was 1,145 tons for which 97.5 tons of coal were required or 8.5% of the ore. The furnace was handled by three men

Fig. 3.—Vertical Sections. C-D, E-F.

#### THE CERMAK-SPIREK FURNACE FOR CALCINING AND ROASTING ZINC ORES.

working in 8-hour shifts and two boys. The total costs amounted to 5.51 fr. per ton of ore. During December, 1901, the furnace was used for roasting zinc blende, but the results are not available for publication at this time. Dimensioned illustrations of the original form of this furnace will be found in *THE MINERAL INDUSTRY*, Vol. VI., p. 572.

## MINING AND MILLING IN THE JOPLIN DISTRICT, MISSOURI.

BY FRANK NICHOLSON.

THE depths of shafts in the Joplin district range from 312 ft., the deepest, down to a few feet only; the average depth of the working mines being about 130 ft. The general tendency during the past two years has been toward a greater depth and there are more mines operated below the 150-ft. level to-day than ever before. The mines do not become richer with depth nor is there any appreciable falling off in the values; it is quite noticeable, however, that at increased depth, the iron pyrite gives out and the resulting zinc concentrates are of higher grade than those produced from the upper levels of the same property. At the present time the total number of shafts in the district, including those abandoned, runs well up into the thousands. Of these there are probably 750 being operated.

## MINING.

There has been a definite decrease in the cost of mining ore since the year 1899, and while the cost of supplies and labor is practically unchanged, there has been a steady improvement in methods and more attention has been given to economic handling. The general character of the work also has improved; the timbering is more substantial and more accurately placed with reference to the stress to be withstood, faces are usually carried larger where due regard to safety will permit and the general administrative talent is more efficient. It is rare at the present time to see a property where the total charge for mining and milling exceeds \$1 per ton of mine-dirt, yet it was not infrequent three years ago to find the working charges as high as \$2 and even \$3 per ton of mine-dirt handled.

The total production of the district for the past three years is given in the subjoined table as follows:—

| Year.     | Zinc Ore.   | Lead Ore.  |
|-----------|-------------|------------|
|           | Lb.         | Lb.        |
| 1899..... | 511,657,470 | 48,212,720 |
| 1900..... | 484,600,410 | 59,013,390 |
| 1901..... | 516,612,270 | 70,530,450 |

These figures show that while the production of zinc ore for the year 1901 was slightly in excess of 1899 and considerably in excess of 1900, the increase was practically unimportant and not at all in accordance with what naturally might have been expected. While a number of new properties are being developed from time to time, others are being exhausted and abandoned. Some of the best producers in the list of 1899 are now making no "turn-ins"; and in other cases the production has fallen off to insignificant figures. These results are partially accounted for by the fact that the year 1899 was one of phenomenally high prices, averaging for the whole year above \$40, while since then the average price has been about \$25 a ton. Prospecting in 1899 was stimulated and many properties were worked at an actual loss, even with the high prices then ruling. At the

present time the industry is on a safer and more substantial basis and it seems reasonable to look for a steady improvement in the future. No sensational increase in production however can be expected until there is another meteoric rise in price which will permit the profitable operation of lower grade ore bodies.

An important change in the methods of mining has been the increased use of machine drills. In 1899 few mines outside of the blanket-vein district of Prosperity used air drills; while at present they are used in most of the hard ground properties, and on one 80-acre tract near Carterville 20 machines are in operation.

The drainage of the mines has become less and less burdensome as the underground reservoirs have become gradually emptied. In fact, as will be mentioned later in this article, there is good reason to believe that within the next five or ten years the mines will not furnish sufficient water for use in the concentration of the ore; in some respects, however, this condition has its advantages, as it will enable the miners to operate the deeper levels. In the early days of Joplin, the Cornish pump, locally known as the "walking beam," was practically the only one to be seen. It cost little to erect a pumping plant of this type, its maintenance was less than that of any other type, and but little technical skill was required. Later the steam pump was introduced and for all emergency purposes it is without doubt superior to the Cornish pump. Still later, when the mines were opened up and the average flow of water ascertained, it was found that no other pump could compete with one of the Cornish type in the cost of maintenance and regularity of action. Its superiority is not only shown in the developed mine, however, but even in sinking, unless the flow of water should fluctuate excessively. Even in this case the Cornish pump for ordinary work, with a good sinking pump in reserve, is to be preferred to the steam pump alone.

With regard to the geology of the Joplin district, but few papers of real merit have appeared among the many written. A continued study of the district and an examination of a large number of surveys of the underground workings confirm me in my belief, as expressed in 1899, that these deposits are all of the cavern type. They are more or less irregular and approximate in shape the limestone caverns of other districts; the only difference being that they have been filled with zinc and lead sulphides which have cemented together the fragmental masses of flint which have fallen into the caverns after the limestone had been dissolved and removed by water carrying carbonic acid. It seems reasonable to believe that all the ore was originally deposited as sulphide, though evidence is at hand not only of the oxidation of the sulphide to carbonate and silicate, but of the reverse of this process on a small scale; that is, the solution of the oxidized forms as sulphate and their redeposition as sulphide by means of the hydrogen sulphide resulting from the decay of organic matter. It not infrequently happens that pick handles are found in the old workings encrusted with small crystals of zinc sulphide (jack). This is pointed to triumphantly by the tyros as evidence that all the ore in this district was derived originally from the oxidized forms, while as a matter of fact it does not prove it, but simply indicates that the process is possible.

## MILLING.

The year 1899 was the culmination of one of the periodic booms that have visited the Joplin district from time to time. Ore prices soared from \$28.40 a ton in January to \$55 a ton in April. The result of this fluctuation in price was that the more enthusiastic and visionary among the operators and promoters threw discretion to the winds and even the most conservative found it difficult to retain their equipoise in the midst of the rush for properties and the astounding prices paid for lands that had hitherto lacked tenants at any price. New 10-year leases were executed and sold at surprising figures for cash. The natural result of this state of things was that many mills were erected on leases that did not justify the expenditure, and, as a consequence, the traffic in second-hand mills during the past two years has been vigorous.

A careful enumeration of the mills in June, 1901, showed 527 concentrating plants with an average capacity of 100 tons each per 10-hour shift. Of these mills, 300 were running with more or less regularity; while the others were idle, the ground on which they were located being barren of workable bodies of zinc ore or unable to pay expenses at the existing low price for ore. A large number of second-hand mills came into the market and the ruling price for a standard 100-ton mill dropped to \$2,000. Many mills of inferior construction were sold at even lower prices, some selling as low as \$750. A very large number of mills have been moved from non-paying properties to others of more promise, and at the present time it is unusual in this district to erect an entirely new mill. Second-hand plants are torn down, moved and re-erected at a cost of from \$1,000 to \$2,500 each, depending upon the size of the mill, length of haul and the weight and character of the machinery. Under this condition the total cost of a new mill is about \$5,000, while if ordered direct from the foundry, the contract price would be not less than from \$7,000 to \$8,000.

Few innovations have been attempted in mill building during the last three years. The most interesting of these is the large brick mill and central power plant erected on the Missouri Zinc Fields' property by the Franklin Engineering Co., of New York. The power plant is equipped with the engines of the Corliss type and generators built by the General Electric Co. The mill machinery is furnished by the E. P. Allis Co., of Milwaukee. The jigs are located on the second floor of the building, and the jig cells vary from the ordinary Joplin type in being shorter in the direction of the flow of the tailings and of excessive width. This mill had to be entirely revamped and was made practically of the Joplin type before it would do the work satisfactorily. After being altered it was able to treat 70 tons of mine-dirt a shift. The mill cost approximately \$46,000, while the best Joplin mill can be erected for about \$8,000. The Joplin type will treat 125 tons of mine-dirt per 10-hour shift and makes a fairly clean tailings. At present the mill has been idle for more than a year, and it will probably never be operated by the company. The Franklin Engineering Co. also designed the Devonshire mill which recently burned. This mill cost about \$12,000 and like the Missouri Zinc Fields' mill it had to be changed to the ordinary type before it would successfully handle the ores of this district.

As emphasized in a previous paper, the treatment of Joplin ores has been evolved by long and patient effort. Almost every conceivable device has been tried and the good features of each retained, while those devices proving unsatisfactory have been discarded. It has been a natural evolution and the present standard mill, while leaving from 1 to 1.5% and even higher values in the tailings, is distinctly superior to any other type of concentrating plant for the special work to be done.

During 1901 a new type of jig, known as the "New Century Quick Drop Jig," has been invented and tested very successfully at Joplin, producing high grade concentrates and clean tailings on almost every sample treated. The plunger of the ordinary jig is actuated by an eccentric which gives it a uniform motion from one end of the stroke to the other, while the new jig is actuated by a spiral cam giving a uniform motion to the upward movement of the plunger and a sudden quick movement to the downward stroke (see Figs. 1 and 2). The results obtained in exhibition tests with this jig have been surprisingly good. There is no mill in the district, as far as is known to me, that is equipped with these jigs, the Cooley type being generally employed.

Further progress has been made in the separation of iron pyrite from zinc blende, and two plants are working along the same general lines, although using different devices. Both give the concentrates to be treated a short, hot roast which changes the pyrite to ferric oxide and affects the zinc ore but slightly. The roasted concentrates are cooled and passed over an electric separating machine which takes out the iron oxide. One plant is in operation near Joplin and the other at Webb City. Both accomplish a clean separation at a cost of about \$2 per ton of concentrates treated.

There has been a general increase in the steam plants erected during the past year. Three years ago it was rather unusual to find mills with more than one boiler, and at the present time nearly all of the newer mills are equipped with two 80-H.P. boilers, which enables them to run more continuously than heretofore.

Another variation in practice which has resulted from the extra grate surface is that many mills burn either mill-run coal or slack, while formerly mine-run coal was almost invariably burned. The Joplin district is especially favored in the matter of fuel, as the eastern tier of counties in Kansas, adjoining this district, produces a large amount of coal which is sold at the pit's mouth at prices ranging from 50c. per ton for slack to \$1.50 for mine-run.

The average freight rate throughout the district is 60c. a ton. The average fuel consumption is 2.5 tons per shift per mill of mine-run coal and about 3.5 tons of slack. The fuel cost per shift therefore ranges from \$3.85 for slack to \$5.25 for mine-run. In some cases a small amount of cord wood is burned in connection with the slack.

In former years the ground being but partially drained, large quantities of water were available in almost every section where milling operations were carried on. As the mining progressed and the number of pumps multiplied the ground became gradually drained and now one of the most serious questions to be met is that of securing sufficient water for washing purposes. On the average

---

to treat the mine-dirt of this district under the system now in vogue ten times the weight of water is required.

Nearly all of the mills have settling ponds and use the water repeatedly, the only loss being that resulting from seepage, evaporation and moisture remaining in the tailings, which averages in all 20% of the total amount used; in other words, a 100-ton mill requires an additional 200 tons of water added to its supply

Portions cut away to illustrate the details of construction.

FIG. 1.—THE NEW CENTURY JIG.

ponds each day. In many cases water is being purchased by the plants at the rate of from 8 to 10c. per 1,000 gal., and the City water works and a number of private firms do a lucrative business in this field. It is the opinion of many operators that within the next five years the water question will have become vital, and most of the plants will have to purchase their water supply. It is the invariable rule in every section of this district that as mining proceeds the underground reservoirs are gradually drained and the pumping difficulties diminished.

From time to time a number of mills have been built in the Joplin district

th capacities ranging from 200 to 300 tons. These, however, have in all cases  
n less successful than the standard 100-ton mill.

Manganese steel roll-shells have been tried in this district with excellent results;  
t are not however used extensively for the reason that on ordinary ores they tend

Cross section illustrating the drop-motion plunger's mechanism and ore bed draw-off.

FIG. 2.—THE NEW CENTURY JIG.

wear as smooth as glass. One set of these shells at Aurora have worn more  
in a year and are still in good condition, having crushed approximately 30,000  
lb of mine-rock. The most popular shell and the one in general use is of chilled  
iron made by a local foundry. These shells wear on the average about three

months, and as they cost about one-fifth as much per pound as the manganese steel sheels, they are generally preferred by the operators.

In a district like Joplin there is naturally a large number of mine superintendents, who, as a rule, are not engineers, nor even men of the highest grade of intelligence. Most of these men have come from the East, where they have hitherto followed some other calling not in any way identified with mining, and when they reach Joplin they have everything to learn. Fortunately, there is a supply of thoroughly competent ground men to be had in this district, who have worked in the mines all their lives and have frequently operated leases on their own account and are endowed with a skill and shrewdness which render them very valuable as mine and mill foremen. The native Missourian is a good worker and a shrewd bargainer, frequently over-shrewd, and it not infrequently happens that a superintendent without any experience whatever is enabled to operate a mine successfully with the help of one of these capable natives. However, in this as in all other departments of industrial effort, technical knowledge and skill are coming to be more and more appreciated. The mine superintendent of the future will be a technical graduate and this will have its beneficial effect in the future development of the district.

## PROGRESS IN PYRITIC SMELTING DURING 1901.

BY FRANKLIN R. CARPENTER.

THE most important application of pyritic smelting during 1901 has been made by Herbert Lang to the smelting of arsenopyrite ores of the Blue Dick mine, at Prescott, Ariz. These ores consist essentially of a mixture of quartz and mispickel, associated with small quantities of iron pyrite, galena, chalcopyrite, tetrahedrite, barite, and spathic iron. The ores are sorted so as to contain about 45%  $\text{SiO}_2$ , and 17% each of Fe, As, and S, the balance being Pb, Cu,  $\text{CO}_2$ , etc., and to the mixture is added about one-half its weight in limestone. The slags were made very siliceous to insure the complete decomposition of the arsenopyrite and the volatilization of the arsenic, thereby avoiding the formation of speiss, which would otherwise occur. The smelting was done in a small furnace of peculiar construction, covered by patents which, however, is not essential to the process. Equally good results could doubtless have been obtained in an ordinary furnace. The slag was of the following composition:  $\text{SiO}_2$ , 40 to 45%; FeO, 24 to 27%; CaO, 20 to 24%, S, etc., to balance. Nearly 90% of the iron was oxidized and slagged, 94% of the sulphur was carried off with the furnace gases or passed into the slag, and the whole of the arsenic was volatilized. The furnace was 3 ft. in diameter, and treated more than 50 tons of ore per day, using a light and cold blast. Mr. Lang is of the opinion that under proper conditions with a hot blast the capacity could be increased to 100 tons or more per day.

A plant has been erected at Rapid City, S. D., under the supervision of Theodor Knutzen; to smelt the siliceous ores of that section, which are similar to those smelted first at the Deadwood & Delaware plant, at Deadwood, S. D., and later by the Golden Reward Co., as described in THE MINERAL INDUSTRY, Vol. IX. The Rapid City plan differs from the one at Deadwood, as it will use a heated blast, and limestone for flux instead of dolomite.

B. F. Morley has rebuilt the old Buena Vista plant, at Buena Vista, Colo., and is very successful in treating the siliceous gold ores of the Mary Murphy mine. The furnace is 34×120 in. in section at the tuyeres, and the blast is produced by a large Green blower. The ores average  $\text{SiO}_2$  55%, CaO 4%, Cu 0.1 to 0.5%, Fe 4%, MnO 3%,  $\text{Al}_2\text{O}_3$  5%, Zn 8%, Pb 1 to 3%, S 8%, and are smelted with iron pyrite from the Leadville district, carrying an excess of about 38% Fe, and from 0.2 to 0.5% Cu. To the charge is added limestone, so the resulting

slag consists of  $\text{SiO}_2$  41%, Fe 18%,  $\text{CaO}$  18%, with  $\text{Al}_2\text{O}_3$ , Zn,  $\text{MnO}$ , etc., to balance.

At Keswick, Cal., the pyritic process has been used to smelt the heavy chalcopryrite ores of that section, and while very promising, it has not yet been wholly successful. The first plant for the treatment of these ores by the pyritic process was built a few years ago by Herbert Lang, with the intention to smelt the ores raw, using a blast heated by the molten slag. Later the ordinary German process of roasting and subsequent matting was used, which offered no difficulties metallurgically, but proved unsuccessful financially. There was a change of superintendents, and a return was had to raw smelting, this time heating the blast by the ordinary U-pipe stove. During the prevalence of high prices for copper, the raw smelting process at Keswick was claimed to have been successful, both financially and metallurgically, and the grade of matte made was as high as that produced by previously heap-roasting the ores. Seven large furnaces, each with its own hot-air stove, were erected but for some reason a return was recently made to a preliminary heap-roasting of at least a part of the ore charge, showing that while raw smelting may be theoretically correct, the mechanical difficulties of the process are often well nigh insurmountable. Through the courtesy of D. H. Conolly the following notes have been communicated of a run of 168 hours upon the No. 4 furnace at Keswick, Cal.:—

DAILY RECORD OF 168-HOUR RUN AT NO. 4 FURNACE, AT KESWICK, CAL.,  
DECEMBER 21 TO 28, 1901.

| Day of Month. | Crude Ore. | Raw Matte. | Porphyry. | Limestone. | Slag. | Coke. | Copper Contents of Matte Produced. |        |

| 27.....       | 145.5      | 18.6       | 37.6      | 7.5        | 56.1  | 4.17  | 19.8                               | 21.3   |
| 28.....       | 37.5       | 5.1        | 8.7       | 1.1        | 14.8  | 1.35  | 20.4                               | .....  |
|               | 1,376.5    | 77.4       | 283.2     | 91.5       | 416.7 | 35.00 | Average.                           |        |
|               |            |            |           |            |       |       | 18.7                               | 19.5   |

Total burden..... 2,146 tons.

Coke used..... 35 tons.

The blast was heated to  $600^{\circ}\text{F}$ ., and the total cost (for furnace work and fuel—excluding office expenses, power, and cost of flux) was, for the entire run \$1,487.50, detailed as follows:—

|                                      |         |                   |
|--------------------------------------|---------|-------------------|
| 35 tons coke.....                    | \$13.00 | \$455.00          |
| 75 cords wood for heating blast..... | 3.50    | 262.50            |
| Labor, seven days.....               | 110.00  | 770.00            |
|                                      |         | <u>\$1,487.50</u> |

These costs per ton of burden are:—

|                    |               |
|--------------------|---------------|
| Coke.....          | \$0.21        |
| Heating blast..... | 0.12          |
| Labor.....         | 0.36          |
|                    | <u>\$0.69</u> |

The amount of coke used was 1.5% of the total burden, or 2.5% of ore and matte charged.

In analyzing the above report it must be remembered that the ores are mixtures

of massive pyrite, and chalcopyrite, yielding a low content of copper, and that silica in the form of "porphyry" is added to slag the iron in the charge, a case which is the reverse of that at Buena Vista, where pyrite is added to the charge.

At Golden, Colo., I recently erected a plant for the treatment of the siliceous ores of Gilpin County, and as these ores are the typical iron sulphide of ordinary fissure veins, a full description may not be out of place. The ores consist of the altered granitic country rock, and iron pyrite, carrying small amounts of copper, gold and silver. At the mine they average 50%  $\text{SiO}_2$  and 6%  $\text{Al}_2\text{O}_3$ ; the remainder being considered as essentially iron sulphide. These ores resemble those at Butte, Mont., except that the principal value is gold instead of copper. The usual treatment of ores of this character is to mill and amalgamate them for the gold, and subsequently concentrate the sulphurets, which are sold to the smelters. More recently amalgamation has been omitted at many mills, the ore being concentrated by jigs, or upon tables, and the resulting concentrates sold,—a treatment which is similar in all respects to that used at Butte upon copper ores. Owing to the losses inherent in water concentration, I proposed to smelt these ores direct as they came from the mine.

The recently completed plant is equipped with boilers, engines, pumps, dynamos, ore bins, etc. The furnace is  $3 \times 16$  ft. in section at the tuyeres, and has a 13-in. bosh in 5 ft. height, above which the walls extend vertically to the top of the shaft. The distance from the furnace floor to the feed floor is 22.5 ft. There are 16 tuyeres upon each side of the furnace, bushed down to 3-in. openings. A No. 8 Connersville blower is used, which displaces 100 cu. ft. of air at each revolution, and is usually driven at 125 revolutions per minute. The stove is of the ordinary U-pipe style, consisting of 60 pipes, each 12.5 ft. in length, and 8 in. in diameter. Twelve tons of cheap lignite coal are consumed in 24 hours, and 12,500 cu. ft. of air is heated to a temperature of about  $700^\circ\text{F}$ .

The charge consists of 1,000 parts of siliceous pyrite, 600 parts of limestone, 200 parts of clean pyrite, and 180 parts of coke of very poor quality. Under favorable conditions, 300 tons of this charge are smelted in 24 hours. Limestone has been almost excluded at times, and the quantity of coke much diminished, pyrite being substituted for it, but the results were not satisfactory. The furnace is tapped from the end, and is probably the longest furnace in the world so tapped. The molten contents flow into a cast-iron forehearth,  $4 \times 6 \times 2.5$  ft. deep placed on wheels, and the best results are obtained when the silica in the slag is kept between 40 and 45%, which is maintained by increasing or diminishing the quantity of clean pyrite used, to conform with the increase or decrease of silica in the ore. The matte is very low in copper, seldom exceeding 8%, and sometimes falling as low as 2%, yet the slags are exceptionally clean, and it is well to note that this result is, apparently, not dependent upon the percentage of copper present. The plant has now been running a sufficient time to know that it can more than compete with the older processes heretofore employed upon these ores.

There is much misunderstanding current regarding the pyritic process, which is kept up especially by those who have "patented" schemes for disposal. It cannot be too strongly urged that, while some of the patented devices may be of value,

there are no essential patents to deter any one from using the pyritic process. It is also well to remember that, while there have been brilliant successes, the greater number of pyritic plants have failed. Those which formerly existed at Boulder and Toston, Mont., and at Leadville, Kokomo, and Ward, Colo., have all, from one cause or other, ceased to run. The large plant at Florence, Colo., has not come up to expectations.

The cases in which the process is most successful are those that approximate the pyritic smelting as described by Dr. John Percy, in which pyrite is added simply as a carrier or collector for precious metals. When pyrite is added for any other purpose, *i.e.*, for a fuel or a flux, it is liable to melt and run away from the charge, leaving the siliceous contents unfluxed, which results in a frozen furnace. This was probably the difficulty at Keswick, Leadville, and other places where the smelting of pyrite ores with little or no carbonaceous fuel has been attempted. The necessary amount of heat-producing constituents is undoubtedly present, if it would only burn, but pyrite is treacherous, and is liable to run away at the first application of heat. At Prescott, Ariz., and at Golden, Colo., the pyrite is so intermixed with quartz that it is held until it is oxidized. I have smelted many thousand tons of Butte copper ores at the Deadwood plant, and have no hesitancy in stating that the whole of the concentrating and roasting machinery employed around the Montana smelting works is unnecessary, provided the process of pyritic smelting is employed that was first developed at Deadwood, S. D. While the ideas there used were in the main derived from European practice, the process was so far modified as to deserve to be known as a distinctively American method of smelting. Many previous attempts had been made to smelt in large blast furnaces a charge consisting of silica, limestone and pyrite, but without success until it was accomplished at Deadwood. At Golden, Colo., the Deadwood practice was materially improved by the addition of hot air, without which pyritic smelting should not be attempted. The process now appears extremely simple, but it has required many years of anxious work and costly experiment to make it so.

## THE PROGRESS OF METALLOGRAPHY IN 1901.

BY ALBERT SAUVEUR.

THE introduction of metallographic methods into industrial works in the United States is to be traced to the year 1891, when a metallographic laboratory was installed at the South Chicago Works of the Illinois Steel Co. Since then the interest taken in the subject has grown steadily until at present there are few steel producers which do not submit their products to microscopic examination. Educational institutions also have given due recognition both to the scientific interest and to the industrial value of metallography, and the subject is now taught in nearly all of our important technical or scientific schools.

Large consumers of metals have not as yet come to realize the value of the microscope as a testing implement that will help them in ascertaining the quality of the metals they receive from the producers, and especially in securing better, safer, and more uniform materials. That this appreciation must come is, however, certain.

It is also disappointing to note the indifference of manufacturers of cast iron castings toward metallographic methods. The usefulness of these methods in connection with foundry work is very great; indeed it opens up a field fully as promising as in steel making and steel working.

This growing interest in metallography, just alluded to, continued unabated during the past year. Many new recruits have been made, and the results of some excellent experiments have been published. The interest taken in the subject by manufacturers of alloys calls for special notice. It should not, however, cause surprise, for I believe that in no other field will metallography prove of more valuable assistance than in the production of alloys. To those who are familiar with the little that has been accomplished, it must be evident that the value of metallography could here be hardly overestimated.

In the following pages are presented the most important developments of the past year.

*Apparatus.*—The requirements of the metal microscopist, who deals with opaque objects, are so different from those of the ordinary microscopist, that the microscopical appliances on the market were not well suited to his purpose. Special stands and special accessories had to be devised in order to meet his needs.

---

In the accompanying illustration (Fig. 1) will be seen one of these special outfits, including all the best devices that have been thought of to facilitate the manipulations and to increase their efficiency.

On the light table will be seen a special microscope stand, eye pieces, objectives and other accessories, as well as a camera and a Welsbach lamp and condenser. A wide range of work may be covered with this simple outfit, the Welsbach lamp and condenser yielding a very satisfactory illumination for low and medium high powers. In many instances it is all that is needed. On the dark table will be seen a similar microscopical outfit together with an illuminating outfit consisting of an arc lamp and a complete optical bench. The optical bench includes two large condensing lenses, one water chamber, and one large diaphragm. The microscope is placed on the base of a vertical photo-micro camera. On the right is a rheostat through which the current is made to pass before entering the lamp. This illuminating outfit yields an ideal illumination, of great intensity and steadiness, unobtainable by any other combination. It is the only arrangement by which it is possible to throw the image of the specimen directly upon a screen. The structure of the samples may in this way be examined by any number of observers simultaneously, discussed at leisure and with greater profit. The direct projection affords also an excellent means of drawing the structure, greatly superior to the use of the camera lucida. The image seen on the screen represents the structure of medium hard steel as it appears when projected upon it. The original magnification was 500 diameters.

With the assistance of a special polishing machine, it does not require, in the majority of cases, over 15 minutes to polish and otherwise prepare a sample of metal for microscopical examination. The image of the structure may then be thrown upon a screen or photographed if desired. The exposure required with the electric illuminating outfit varies from one to five seconds. By using Carbutt's process plates and drying with alcohol, the negative may be ready for printing within half an hour after the sample has been taken in hand. With a Welsbach lamp the time of exposure is, of course, considerably longer.

*Crystalline Structure of Metals.*—Prof. J. H. Ewing, of the University of Cambridge, and Mr. Rosenhain have published<sup>1</sup> a very interesting paper on the crystalline structure of metals. From the fact that the structure of hardened steel, i.e., of steel suddenly cooled from a high temperature, is totally different from the structure of the same steel allowed to cool slowly, it is rightly argued that the structure of steel at a high temperature differs greatly from its structure at a lower temperature; that upon slow cooling important change or changes occur in the structure. Again, on reheating a piece of steel past the critical point it is well known that all pre-existing structure is obliterated and replaced by a new crystalline arrangement. It thus appears that spontaneous changes of structure occur in steel, both on heating and cooling. These structural changes, however, have never been observed *while taking place*; the inference that they do occur is based entirely upon the appearance of the cold metal, that is, of the metal *after* the change has been consummated; hence a natural longing to

<sup>1</sup> Philosophical Transactions of the Royal Society, Vol. XIX., p. 279; also, *The Metallographist*, Vol. V., p. 72.

observe these structural transformations while actually taking place. Every metallographist has probably brooded more or less over this problem, and in nearly every instance was probably led to the conception of what appeared the most promising method of solving it, namely, the microscopical examination of a polished and etched steel section while being heated by an electrical current forced through it, and surrounded by a non-oxidizing atmosphere so as to prevent the formation of an oxidized film over the etched surface. The experiment was actually tried by several investigators, but the many mechanical difficulties encountered were not successfully overcome. Messrs. Ewing and Rosenhain were more successful. With great experimental skill they mastered the purely mechanical difficulties, but the results which they report are indeed disappointing. No change of structure could be detected under the microscope while the metal was being heated or cooled under the conditions just alluded to. Upon a very slight re-polishing and re-etching of the sections, however, the structure was found to have undergone the change which was expected. While a structural transformation occurs within the metal, therefore, the pattern of the surface remains unaffected, hiding the change and preventing its observation. The authors very clearly explain this unexpected result in the following words: "The explanation is obvious when we realize that the pattern seen in the microscope is due to the differences of level and texture in the surface of the specimens which have been produced by the action of the acid used in etching. This pattern, although in its origin dependent upon the actual crystalline structure of the metal at the time when the surface was etched, remains as a mere mask, beneath which re-orientation of crystalline elements may go on without affecting its appearance. The etched pattern is in this respect in the same position as a scratch or mechanical marking of the surface, and the persistence of the etched pattern after annealing is simply an extension into more minute detail of the well-known fact that the external shape of a piece of metal is not in general affected by annealing, although the crystalline structure is entirely changed. These considerations show that we cannot expect to see the process of recrystallization in any metal where etching, staining, or relief polishing is needed to differentiate the constituents."

Failing thus to observe structural transformations in iron and steel, the authors turned their attention to the process of recrystallization in more fusible metals, such as lead, tin, zinc, and cadmium. They observed that sheet lead, when properly etched, exhibited large crystals and very frequently twin crystals. A lead surface must be kept wet with an acid solution while it is being examined and photographed, as such a surface becomes dull and useless as soon as it dries. Sheet lead is rolled cold from cast ingots, and yet the crystals of sheet lead exhibit no distortions whatever. We must conclude from this that a recrystallization of the metal took place after the rolling at atmospheric temperature. To throw more light upon this point the authors investigated the changes of structure occurring in cast lead through severe straining, cast blocks of lead being squeezed in a compression testing machine. Fig. 2 shows the structure of cast lead magnified 12 diameters, and Fig. 3 the structure of freshly crushed lead magnified 30 diameters. The specimens of crushed metal were then

examined at intervals during a period of six months to ascertain whether any change of structure was taking place spontaneously at the ordinary temperature. A decided growth of crystals was detected by actual measurement, although such growth is not evident from the appearance of the photographs taken by the authors respectively after six days, one month, four months, and six months. The manner in which the crystals grow is described as follows: "It is seen that the crystals do not grow by the steady accretion of layers all over their surface, but that they throw out arms or branches, which invade neighboring crystals, thus forming a skeleton crystal somewhat similar to those that are often noticed in the crystallization of fused substances."

The authors then subjected samples of sheet lead to a temperature of  $200^{\circ}\text{C}$ . for varying lengths of time, in order to ascertain whether it would result in further crystal growths. "Our observations," the authors say, "show that the metal in this state is very sensitive to moderately high temperatures, three minutes' exposure of ordinary sheet lead to a temperature of  $200^{\circ}\text{C}$ . being sufficient to produce a great change in the crystalline pattern. If the specimens be kept at  $200^{\circ}\text{C}$ . for a long time there is a continued change, but it becomes very slow, and ultimately a state is reached when further change is imperceptible."

Fig. 4 shows the structure of sheet lead magnified 12 diameters; Fig. 5 the structure of the same sample after maintaining it at  $200^{\circ}\text{C}$ . for six days. The triangular markings seen in the photographs are deep scratches made in the polished surface in order to be able to photograph exactly the same spot before and after the annealing treatment.

Freshly crushed lead was then heated to  $200^{\circ}\text{C}$ . and kept at that temperature for a long time. This treatment resulted in a very marked growth of the initially small crystals, some very large ones being detected in various parts of the specimens. The authors' conclusions concerning the recrystallization of lead are as follows:—

- (1) "In lead which has been severely strained recrystallization goes on at all temperatures, from that of an ordinary room up to the melting-point.

- (2) "The higher the temperature the more rapid are the changes in the crystalline structure.

- (3) "The rate of change varies with different specimens, probably depending upon the nature and quantity of impurities present and upon the severity of the strain to which the metal has been subjected.

- (4) "The size of the crystals ultimately produced does not vary appreciably between  $100^{\circ}\text{C}$ . and  $300^{\circ}\text{C}$ . In lead annealed at the temperature of the air, very large crystals have not yet been obtained, but this is probably only a question of time.

- (5) "The phenomena of growth of crystals occur in lead only when the metal has previously been subjected to severe plastic strains. The structure of a cast specimen remains unaltered at temperatures which cause a strained specimen to show rapid change. By casting in a mold arranged to cause rapid cooling, specimens of lead can be obtained having a minute crystalline structure, whose scale is not very different from that of severely crushed lead; such a specimen was exposed to  $200^{\circ}\text{C}$ . for nearly seven days, but no visible change of

structure occurred. A piece of this specimen was then strained by severe crushing, and on further exposure to 200°C. vigorous growth took place.

(6) "The rate at which a lead specimen is cooled from temperatures of 200°C. to 300°C. down to ordinary air-temperature has no visible effect on the structure. Even 'quenching' in liquid air has no visible effect; quenching in water, cooling in air, and slow cooling in the oven were all tried on a number of specimens without in any way affecting them.

(7) "Lead is mechanically hardened to a small extent by severe strain, and the subsequent effect of annealing in restoring softness is correspondingly small. In one of the experiments a specimen of lead was crushed under a given load in the testing machine, and the load was left on until no further creeping occurred. The specimen was then annealed and again placed under the same load, when a distinct amount of further crushing was seen to take place."

The authors ascertained next that tin, zinc and cadmium, after being severely strained, recrystallize very much like strained lead. The striking crystalline structure of tin plate is well known, and is illustrated in Fig. 6 (one-half natural size). It will be noted that individual grains are not uniformly dark or bright, but that the brightness shades off across the grain. This appearance is unlike that observed in the crystalline grains of other metals, and we are led to infer from it that in these tin grains the orientation of the small crystals of which such grain is composed is not uniform all through the grain—in other words, that these grains are not true crystals, since constancy of orientation of the elements is an essential characteristic of a true crystal. The authors, however, are inclined to attribute this feature to "a distortion or bending of true crystalline plates; such distortion would probably arise from differences in the coefficients of expansion of iron and tin brought into action by a suitable rate of cooling. Considering the extreme thinness of the layer of tin, the amount of distortion might well be purely elastic and insufficient to produce slip in the crystals of tin."

Seeing that it is generally supposed that recrystallization in iron and steel occurs at the thermal critical points, the authors endeavored to ascertain the existence of such critical points in lead, tin, zinc and cadmium. Failing to detect any they express their doubt about the relation supposed to exist between the structural changes and the critical points of iron and steel. This doubt hardly seems justified. It has been most conclusively shown that if a piece of high-carbon steel be heated below its critical point, no matter how near to that point, its structure remains unaltered, while if it be heated just above it, its structure is deeply changed. Again, if it be quenched just before reaching the critical point it is not hardened, while if it be quenched just above it, it is fully hardened, and this acquisition of the hardening power implies a radical change of structure. Are these not conclusive evidences of the close relation existing between the critical points and accompanying structural changes? They are both the manifestations of the same transformation. Again the authors overlook here a momentous difference between the recrystallization in lead and tin such as they have observed, and recrystallization in iron and steel. They state repeatedly and emphatically that in the former metals recrystallization takes place only in strained samples, while it is well known that the structure of cast

steel is affected at the critical points as well as that of forged, drawn, or otherwise strained metal. This suggests a difference of origin between the structural changes in steel and those in other metals.

To account for the growth of crystals in metals at low temperatures, the authors proposed an ingenious and most interesting explanation. They argued that even so-called "pure" metals always contain a certain amount of impurities, and that some of them combine with a small amount of the metal itself to form eutectic alloys, that is, alloys which have a lower melting-point than the metal. "It is well known that when a metal containing a small proportion of such impurities crystallizes, the impurities are, for the most part, segregated in the intercrystalline boundaries. The crystals themselves form at a temperature when the eutectic alloys are still quite fluid, and the growing crystals gradually push the remaining eutectic into the boundaries. When the quantities of impurities present is sufficiently great, this eutectic can be seen under the microscope forming an intercrystalline cement. . . . When the quantity of eutectic present is very small, the meshes of intercrystalline cement cease to be visible, but the presence of the impurity makes itself felt by the formation of deep grooves or channels along the intercrystalline boundaries, on etching. Even a very minute amount of impurity would suffice to form a thin but practically continuous film of eutectic in the crystalline boundaries."

The authors contend "that there is constant diffusion upon the surface of the crystal into the eutectic and equally constant re-deposition of metal upon the crystal from the eutectic film. If there are several crystals in contact with the same eutectic, then there will be, under some conditions, a state of dynamic equilibrium between them, the amount dissolved from each being exactly counterbalanced by the amount deposited upon it; if, however, there is any difference in their "solution pressure" in respect to the eutectic, then the less soluble will grow at the expense of the more soluble. . . . The metal constituting the eutectic films being much nearer its melting-point than the rest of the mass, would thus be favorable to comparatively rapid diffusion, but the rate of such diffusion, and consequently, the rate of growth of crystals, would be enormously increased by heating the metal to a temperature above the melting-point of the eutectic in question."

The theory proposed depends upon the existence of a difference in the solubility of the two crystal faces in contact with the eutectic film. The only difference between these two faces is, apparently, in the orientation of the crystalline elements, but this difference is sufficient, in the authors' opinion, to produce a difference in their rate of solution in the eutectic film, seeing that it results in such marked difference in their solubility in the etching acid, which, as is well known, attacks some grains much more readily and deeply than neighboring ones whose elements have another orientation. To account for the influence of the orientation of the elements upon the solubility of the crystals, the authors suggest to extend to alloys the electrolytic theory of solution. "Such differential actions," they say, "may most probably be attributed to differences of electrical potential in the surfaces involved. If we accept this view of the matter, then the diffusion across films of eutectic becomes a case of electrolysis,"

Fig. 2.  
Cast Lead, magnified 12 diameters.

Freshly Crushed Lead, magnified 30 diameters.

Fig. 6. Etched Tin Plate, reduced to half size.

Fig. 7. Weld in Lead, magnified 30 diameters.

Fig. 8. Weld in Lead, with Eutectic, magnified 30 diameters.

This theory explains why only strained crystals of the metals examined will grow, while unstrained crystals show no tendency to change, even at high temperatures. "The explanation, on the electrolytic theory, is that in the unstrained state the crystals are surrounded by practically continuous films of eutectic, and that electrolysis only becomes possible when severe distortion has broken through these films in places, allowing the actual crystals to come into contact; the electrolytic circuit would then be for each pair of crystals, from one crystal to the other by direct contact and back through the eutectic film."

If the authors' brilliant conception be true, recrystallization by annealing in a perfectly pure metal would not occur, but as they rightly say, it is almost hopeless to obtain a sample of metal sufficiently pure to prove or disprove the theory. They argue, however, that if the growth of crystals is due to the presence of a eutectic film between them, the absence of such film would be a barrier to all such growth, and that a weld between two clean-cut surfaces should show no growth of crystal across the weld. This they actually proved to be the case. Fig. 7 shows the appearance of welded lead after annealing and magnified 30 diameters. The line *AB* shows the weld. It will be noted that the crystals have grown up to the line of the weld and then ended quite abruptly. In no case does a grain cross a weld-line. The weld, therefore, behaved as a true intercrystalline boundary, differing only in the absence of eutectic, and therefore forming a barrier to crystalline growth. The authors then went one step further, and in order to produce a growth of crystals across the weld, in accordance with their theory, they introduced a eutectic film at the weld in the shape of a continuous layer of lead-bismuth, and subjected the sample to annealing to cause the growth of the crystals. No growths, however, took place across the weld, but this they explained on the ground that the eutectic film formed a *continuous* separation between the two lead surfaces, analogous to those forming the boundaries of unstrained crystals, and that a discontinuous eutectic film is required according to the electrolytic theory, to cause a crystal growth. Their next step was accordingly to introduce such a discontinuous film at the weld in the shape of a few small flakes of the same alloy. After annealing the crystalline growth was found to have extended over the weld-line as is well shown in Fig. 8, in which *ED* represents the weld. In the center of the field will be seen a large crystal cut almost in halves by the weld.

The results of these experiments with welded lead point strongly to the accuracy of Messrs. Ewing and Rosenhain's theory. Their work is of a masterly character, both as to experimental skill and intellectual power.

*Structure and Finishing Temperatures of Steel Rails.*—It is well known that when a piece of steel is allowed to cool undisturbedly from a high temperature, it crystallizes, and that the resulting crystals or grains, as they are frequently called, are the larger, the higher the initial temperature and the slower the cooling. This was first forcibly stated by Prof. Tschernoff in his masterly paper on "The Manufacture of Steel and the Mode of Working It," communicated to the Russian Technical Society in April and May, 1868.

It is also well known that if the steel be vigorously worked (rolled or forged) while it is cooling from a high temperature, crystallization is prevented, but as

soon as work ceases, crystallization sets in until a certain temperature is reached, which in the majority of cases is not far from  $700^{\circ}\text{C}.$ , and below which there is no further growth of crystals. If work be performed below that critical temperature the crystals are permanently distorted, being flattened and elongated in the direction of the rolling and this distortion of the crystals is greater the lower the temperature at which the work is carried on. Such distortion causes a decrease of ductility and, eventually, brittleness, a striking illustration of which is found in the drawing of wire, which must be frequently annealed to remove the brittleness produced by work at a low temperature. The annealing removes the distortion of the crystals and, therefore, the resulting brittleness by causing the metal to assume a new and finer crystallization.

For convenience, the range of temperature during which steel crystallizes, and which extends from the melting point to the critical temperature (about  $700^{\circ}\text{C}.$  in the case of carbon steel) may be called the crystallizing range, and the work performed at these temperatures "hot work," while the work done below these temperatures will be called "cold work." Hot work influences the final structure by preventing or retarding crystallization, while cold work distorts the crystals.

It follows from the above considerations that in working steel, as is done in the manufacture of so many implements, from a high to a much lower temperature, crystallization is retarded, *i.e.*, is made up to cover a much shorter range of temperature, extending from the finishing temperature (the temperature at which work ceases) to the critical temperature. The resulting structure will, therefore, be finer grained, *i.e.*, will be made up of smaller crystals, than if the metal had been allowed to cool undisturbedly from a high temperature; the crystals will be the smaller the lower the finishing temperature. Should work be continued below the critical temperature the crystals will be distorted, which implies a loss of ductility.

It has been conclusively shown that the finer the structure, *i.e.*, the smaller the crystals, the more ductile will be the steel, and since ductility is always a very desirable property, whatever the intended use of the finished implement, the treatment of the metal should be conducted so as to confer upon it the finest possible structure. The importance of finishing steel implements at the proper temperature, therefore, need not be insisted upon. It is now appreciated by all enlightened metallurgists.

The manufacturers of steel rails, more than any other producers of finished steel articles, have given careful attention to the important influence of the finishing temperature upon the structure and the physical properties of their rails. In these days when the tendency is to allow more and more carbon in rail steel, in order to lengthen the life of the rail, the importance of securing all the ductility possible from the heat treatment stands pre-eminently at the front.

The importance of low finishing temperatures was clearly brought out some ten years ago at the South Chicago works of the Illinois Steel Co., as a result of my extensive tests, which were summarized in a paper presented at the Engineering Congress in 1893. In spite of the conclusiveness of these tests however the management could not be made to take up any efficient measure toward lowering the generally too high finishing temperature of the rails. It was assumed that

any step in that direction would interfere with the output and this was not to be considered. While the results given in the paper did not attract much attention at the time, the importance of proper finishing temperatures gradually asserted itself until at the present day there is hardly a steel rail user or producer who is not fully alive to it. The results of many experiments along this line have been published within the last year which confirm the conclusions reached ten years ago.

*The Kennedy-Morrison Rail Finishing Process.*—The suddenly renewed interest in the subject of proper finishing temperature for steel rails, alluded to above led the Carnegie Steel Co. to a notable departure at its Edgar Thompson plant, from the ordinary mode of procedure. This move on their part was given much publicity and has attracted the attention of all rail consumers. Stated briefly, the modification which they have introduced in the rolling of steel rails consists in holding the rails on a cooling table a few minutes before subjecting them to the last pass. It is argued that by so doing the rail is finished at a lower temperature, which is the desideratum sought.

Looking critically into this new departure in rail rolling, it is observed that the rail, when it reaches the cooling table before the final pass is at a high, or relatively high, temperature and is then allowed to cool until a certain lower temperature is attained. During this undisturbed cooling the metal evidently crystallizes and the rail must necessarily enter the finishing rolls in a crystalline condition, which will be the more pronounced the higher the temperature of the rail when it reached the cooling table and the slower and more prolonged the subsequent undisturbed cooling. It also seems as if the single pass to which the metal is subjected after this crystallizing period cannot be sufficient to break up the crystallization just created. On theoretical grounds, therefore, if a material gain results from this method of procedure, I do not see how it can be accounted for. Let us remember that any undisturbed cooling above the critical temperature constitutes a crystallizing period. By partially cooling the rail before the final pass, the crystallizing range is shortened after the rail has left the finishing rolls, but a crystallizing period is created just before the final pass, which is exactly equal in length to the diminution of the final undisturbed cooling. By so doing the total crystallizing range is not decreased, which alone governs the size of the final crystals; it is merely divided, causing a part of it to be located immediately before the final pass and the balance immediately after, so that a rail treated by this process has passed through a crystallizing period of exactly the same length.

The only beneficial effect therefore that can be claimed for this process is that it breaks up the crystals produced just before the last pass, resulting in a finer structure rail. Assuming that the reduction produced by the last pass is about five per cent. it seems hardly conceivable that so slight an amount of work could be effective in breaking a pre-existing coarse structure.

Similar criticisms of the value of the Kennedy-Morrison process have been published by Mr. S. S. Martin, of the Maryland Steel Co., who contends, apparently on good ground, that any undisturbed cooling introduced in the process of rolling, in order to be effective in producing a finer grained rail, must take place at an early period, because then the considerable reduction, *i.e.*, the great

amount of work to which the rail is subsequently subjected, will break up the crystals formed during that undisturbed cooling. It has also been argued, and rightly, I think, that those mills which do not reheat their blooms produce finer grained rails, for the simple reason that they finish their rails at a lower temperature.

To sum up, in order to confer a fine-grained structure upon steel rails, three courses seem to be opened:—

1. To shorten the crystallizing period, *i.e.*, the time during which the rail is allowed to cool undisturbedly above the critical temperature (say about 700°C.). In other words, the rail should be finished sufficiently cooled, and the finishing temperature will, of course, depend in turn upon the temperature of the ingot when rolling begins and upon the speed of the operations. The main objection to starting and carrying the rolling at a relatively low temperature is that it throws more work upon the rolls. The objection to a slow rolling speed and handling of the material is that it decreases the output of the mill. Both objections imply an increase in the cost of the rail.

2. To cause a part of the crystallizing period to occur previous to the final pass, *i.e.*, to allow the rail to cool undisturbedly at some stage of the operations, and for a short time, before completing the rolling. This cooling in order to be effective should occur at a sufficiently early stage of the rolling, in order that the resulting crystallization may be broken up through a sufficient amount of subsequent work and reduction. Such results would be obtained by placing the cooling table at the shears. The objection to this course is that the shaping of this cooler bloom into rails would require greater mechanical effort and, therefore, increase the cost of production.

3. To finish the rail at the temperature most desirable for easiness and speed of manipulation in rolling and then to reheat it to a temperature slightly above the critical temperature, a treatment which would result in the breaking up of the pre-existing coarse structure, replacing it by a much finer one. This course would undoubtedly be the most effective of the three as it would not only impart a fine structure to the rail, but also a uniform structure to all its parts, while a rail not so treated must necessarily be coarser in the central parts than nearer the cooling surfaces, owing to the higher temperature of the center when the rail leaves the finishing rolls and to its slower subsequent cooling. The cost of such reheating treatment would undoubtedly be very great and, possibly, prohibitive.

*The Constitution of Cast Iron.*—Prof. Henry M. Howe has published a most important paper<sup>2</sup> on the constitution of cast iron, which takes the discussion on that subject out of the pit and obscurity in which it has raged for so many years to place it in broad daylight on a good sound ground. The attitude and arguments of many foundrymen on the subject of cast iron is a source of incessant wonderment to the metallurgist with a logical and scientific turn of mind. It is gratifying to see Prof. Howe begin his article by stating a truth which foundrymen constantly ignore, namely, that there is no break whatever in their properties or structure, in the series of carbonized iron compounds as we proceed from low-carbon steel to white cast iron. It is absolutely in an arbitrary

---

<sup>2</sup> *American Institute of Mining Engineers*, February, 1901; also the *Metallographist*, July, 1901.

way that we decide to call cast iron all compounds containing over 2 or 3% C. It is also refreshing to have Prof. Howe state that gray cast iron is steel plus graphite, *i.e.*, is made up of a matrix of steel of varying carbon content through which are disseminated particles of graphite. The contention so often heard that the laws and reasoning based upon the scientific study of steel cannot be applied to cast iron, because it is such a radically different and more complex metal does not for a minute stand the light of searching inquiry.

Since cast iron is merely steel of varying carbon content, with (gray cast iron) or without (white cast iron) particles of graphite breaking its continuity, we should have no difficulty in inferring what should be the structural composition of cast iron possessing certain desirable properties. We only have to remember that as the carbon content of steel (the combined carbon) increases, the tenacity increases up to about 1%, and then decreases, the ductility decreases continuously and the hardness increases continuously; and that the presence of plates of graphite, breaking up the continuity of the mass decreases both its strength and ductility. Looking upon cast iron, therefore, in the light of what it really is, *i.e.*, a high-carbon steel (white cast iron) or a metal possessing a steel matrix through which particles of graphite are disseminated (gray or mottled cast iron), if we desire to obtain (1) a casting of maximum strength: it should be made up of a matrix containing about 1% of combined carbon with as little additional carbon (either combined or graphitic) as possible, since such additional carbon would decrease the strength; (2) a casting of maximum ductility and softness: the matrix should contain as little carbon as possible, and the metal as little graphite as possible; (3) a casting of intermediate properties: the matrix should contain an amount of combined carbon varying between 0 and 1% according to requirements and the metal as little graphitic carbon as possible; (4) a casting of maximum hardness: it should contain as much combined carbon as possible and no graphitic carbon (white cast iron). It is seen that it is never desirable to have over 1% of total carbon present, but since in cupola practice the amount of total carbon absorbed by the iron can only be controlled between very narrow limits (varying generally between 3.5 and 4%), it is only by regulating the relative properties of combined and graphitic carbon that we are able to approach the properties desired. To do so we must regulate properly the amount of impurities, and especially of silicon, sulphur and manganese present in the iron and the rate of cooling (size of castings, chilling, etc.), since these factors all influence the formation of graphitic carbon or the retention of the carbon in the combined condition.

It also follows that in the so-called "air furnace" in which pig iron is melted under oxidizing conditions, a stronger cast iron can be obtained, since it is possible to decrease the amount of total carbon, and this is confirmed by experience.

## MINE TIMBERING AND THE SUPPORT OF EARTHWORKS.<sup>1</sup>

BY WILBUR EDGERTON SANDERS.

THE term "Earthworks," in its broadest sense, includes many engineering works and the various operations connected with the extraction of materials of economic value from the earth's crust, and it comprehends excavations in solid rock as well as in the looser materials forming a part of the superficial deposits of the earth. Technically speaking, the subject is divided along natural lines into "Engineering Earthworks" and "Mining Earthworks"; the former class dealing especially with construction enterprises, while the latter has for its object the extraction of materials from or from beneath the surface of the earth. While the operations carried on under either of the above branches of the subject are founded upon the same principles yet are their requirements and conditions usually dissimilar, and for this reason the details of the work are often handled in different ways.

Both Engineering Earthworks and Mining Earthworks may be subdivided into three classes: Embankments, or earthworks made by filling; Walls, those made by building and by cutting; and Excavations, those made by cutting. Excavations may be still further classified as of two kinds: Surface Excavations or those open to the sunlight, which include trenches, open-cuts and quarries; and Underground Excavations, comprising those earth-workings that are shut in from the sunlight and which are covered by overlying formation.

All earthworks must in some manner be supported, whether such support is afforded by natural or by artificial means. The natural supports are furnished by the materials of which the works are constructed, as is the case with embankments and walls, or those in or through which the workings are excavated, as when the natural rock enclosing earth-workings is of texture and strength sufficient to resist the pressures bearing upon them. The artificial supports are furnished by extraneous materials applied to resist pressure-forces, in evidence or prospective, and are especially adapted to specific uses.

As regards the science of support, all earthy matter in and through which earthworks are excavated may be divided into two classes that are indicative of

---

<sup>1</sup> A comprehensive treatise on this subject is now being prepared by Mr. Sanders to be published by The Engineering and Mining Journal (Inc.) in the near future. The work will be eminently practical and fully illustrated by plates taken from working drawings, methods in vogue at metalliferous and at coal mines as well as the support of large tunnels, etc.--Editor of THE MINERAL INDUSTRY.

the normal and abnormal physical characteristics of enclosing and supporting formations; for upon these characteristics, as well as upon the nature and extent of the workings themselves, depend in great measure the employment of natural and artificial methods of support. In this classification it is well to assume as of the normal type those rocks that possess such physical characteristics of strength, hardness and density, cohesion and toughness, as shall enable them of themselves to support to a greater or lesser degree the weight and other pressures bearing upon and tending to destroy the workings. On the other hand the abnormal physical characteristics of earthy matter are those which are due to changes, physical, chemical and dynamic, that affect the texture, solidity or coherence of the rocks and rock-masses, rendering them soft and often even fluid or causing them to separate into parts large or small. Movements of the earth's crust whereby the masses become fractured and broken or crushed, bedding planes, cleavage planes due to pressure and those due to other causes, the circulation of waters that take into solution certain mineral constituents of the rocks and thereby expose them to disintegration, the absorption of water by the feldspars of certain rocks whereby kaolinization takes place and clays are formed, thus causing the swelling ground that presents at once a condition of the greatest difficulty to overcome and one of the greatest dangers to earth-workings; these are but a few of the abnormal features that are developed by excavations in the earthy materials and that must be met and resisted by artificial supports in order that the workings may be kept open and the work prosecuted.

The various kinds of earthworks that must receive natural or artificial support are, as regards surface workings:—

(1) Embankments and Walls; both of which are built up above the surface of the earth, the former usually being constructed of the loose materials of the superficial deposits and depending for support either upon the friction between the different particles of which it is built or upon a retaining-wall of strength sufficient to afford the needed support, the latter constructed of materials of texture and mass possessing strength sufficient to furnish the desired support.

(2) Trenches and Open-cuts.—These workings are very similar in character, the distinction being largely one of relative size. A trench is a narrow cut into the surface of the earth, while an open-cut is a trench of exaggerated dimensions.

(3) Quarries.—Still further differentiating between trenches and open-cuts, as regards the dimensions of the workings, we have the quarry. This class of earthworks may be either of regular or irregular form and though usually of large extent it may nevertheless approach in size to the open-cut. Another distinction lies in the fact that while the quarry is employed for the purpose of "winning" or obtaining materials of economic value at the surface of the earth, and is therefore a branch of mining, trenches and open-cuts have more frequently to do with engineering enterprises.

As regards underground workings the subject of earthworks may be divided into three classes:—

(1) Level Workings.—These are horizontal workings and comprise passageways and stations. Passageways are employed for traffic of various kinds while the stations furnish storage room underground and are also made use of for the

location of mine pumps below the levels that open to the surface. Depending upon the locality, and the uses to which they may be put, level passageways are called adits, adit-tunnels, tunnels, levels, drifts, drives and driveways, tramways, haulageways, gangways, headings, cross-headings and cross-cuts, while stations of the metalliferous mines of the West are known as plats among the coal miners of the East.

(2) Inclined and Vertical Passageways.—These include inclined rectangular shafts, otherwise termed inclines and slopes in the coal regions, and vertical, round, elliptical, polygonal and rectangular shafts, together with those interior mine workings known as raises and winzes.

(3) Extraction Places, oftentimes called Working Places.—These workings are the points at which materials of economic value are attacked and from which they are broken down and extracted. Depending upon the character of the deposit such workings may be horizontal, inclined or vertical. In connection with horizontal and slightly inclined bodies the extraction places are designated rooms, chambers, stalls, and sometimes benches, when the materials are attacked in benches within room, chamber and stall. In the more steeply inclined deposits and when the materials to be excavated occur in large masses, where the surrounding and overlying formation must be supported, such working places are known as “stopes.” Depending upon the method of attack, as to whether the material is broken from above or from beneath, these workings may in turn be subdivided into overhand and underhand stopes.

#### MATERIALS OF SUPPORT.

The materials that are employed for the purpose of supporting earthworks are: (1) Earthy Materials; (2) Metal; and (3) Timber.

(1) Earthy Materials.—All natural support is afforded by earthy materials, wherein the natural rock in place is made use of to resist the pressure-forces bearing upon and tending to destroy the workings. Here the strength and other normal physical characteristics of the rock furnish the needed support, and in the form of walls, slopes, benches, pillars and pillar-arches are often all-sufficient. More frequently, however, artificial support is necessary, and extraneous materials are employed in specific ways to satisfy the demands of the usual and unusual conditions that are continually developing in earth-workings. Here, too, the earthy materials are employed to furnish support, and rock in various forms is used as also are brick and cement. Rock, cut, broken or crushed into stone of regular or irregular shape and size, and used wet (with mortar or cement) or dry (without such binding material), is built up to form walls, arches, and pillars or bulkheads, while crushed or broken stone is roughly dumped into the excavations for waste-filling or more carefully stowed therein for waste-stowing. Finely crushed or comminuted stone or other earthy material, as tailings and culm, is frequently employed to support underground openings and is filled into them by various methods of procedure. Brick is often employed to furnish support to underground workings and is built up with mortar or cement to form walls, arches, and pillars or bulkheads. Cement, also, is used under certain conditions,

and as walls, arches and pillars supports many kinds of earth-workings. All earthy structures that depend largely or entirely upon the maintenance of their proper form in order to offer their powers of resistance to the pressure-forces bearing upon excavations, and of supporting the workings thereby, can be employed only under conditions that favor the integrity of their construction. Walls, pillars and arches, able to withstand the pressure-forces which they are built to resist, quickly fail when subjected to the grinding action of creeping or moving formations.

(2) *Metal.*—Iron is the only metal that is employed for supporting earthworks. In the engineering construction of recent years it has largely supplanted the use of timber, stone and brick, as also has it to a considerable degree taken their place in architectural structures. In the use of the metal underground there are restrictions which prevent it from superseding in large measure the earthy and timber supports that are commonly employed in the deep workings. Subterranean waters are frequently charged with chemicals that are injurious and even destructive to iron structures, and for this reason metal is unlikely to replace to any great extent the other materials of support in regions that contain certain minerals and where the solutions that circulate through the earth's crust in those localities are heavily charged with sulphuric acid, copper sulphate or other deleterious constituents. In some places, however, where iron is used for support it possesses a distinct advantage over timber and the earthy materials and, when intelligently employed, its use may frequently be advantageous not alone from an engineering standpoint but from that of economy as well.

As cast iron, wrought iron and as steel, the metal is available for supports. When cast it is used for props to support the roof in the horizontal and slightly inclined extraction places, for posts or legs and the cap or crown of drift and station, gangway and plat sets, for the sole-blocks of gangway sets, and for the tubbing and bearing-rings of vertical round and elliptical shafts. As wrought-iron it is available for supports when rolled into structural shapes, those which are especially adapted to such use being plates, the flat and oval bars, angle beams, channel beams, H and T beams, and rails.

As soft and mild or medium steel it is available for use as supports when rolled into structural shapes, as angle bars, channel beams, I and T beams, and as rails. Both steel and wrought iron in structural shapes are employed as supports in levels and in shafts, going to make up the parts of the regular drift and gangway and plat sets, to form the metal caissons and air-locks for driving level workings and for sinking shafts in running ground and in watery strata, and they are assembled to make up the framework of inclined and vertical rectangular shaft square-sets.

(3) *Timber.*—For many reasons timber is the most important material from which the artificial supports for Mining Earthworks are constructed; and because of its adaptability to such uses, its applicability in meeting the usual and unusual conditions met with in earth-workings, and the ease with which it may be manipulated, shaped, handled and located, its primary importance as a material for the support of excavations must remain undisputed.

There are two classes of timber in general use for supports: the woods of the

narrow-leaved, naked-seed conifers (pine, fir, spruce, hemlock, tamarack, cedar, redwood, cypress), and those of the broad-leaved trees (oak, ash, locust, chestnut, poplar, cottonwood). Quickly grown hardwoods from rich, warm soils, and slowly grown conifers from high altitudes and the poorer soils, with moderately narrow rings, as a rule yield the most durable woods. The qualities most desirable in timber for supports are strength and elasticity, which characteristics are obtained to a degree in the clear-grained and harder varieties of the conifers. Of two pieces of the same wood the most durable and the stronger is usually the heavier one. Knots and checks within the grain of the wood are sources of weakness, and under end-compression and transverse strain are favorable to sudden breakage without previous warning.

Timber for supporting underground workings should be seasoned where possible before it is placed in position. The main cause of decay in wood is the sap, which sets up a fermentation within the cellular tissues and destroys them; wherefore the trees should be felled when the least amount of fermentable sap is in the wood, usually about December. When the trees are cut down while "in the sap" it is well to leave the tops undisturbed, trimming off the branches only as high up as the log is desired for use as timber. By so doing the leaves in effect act as a suction-pump, drawing the sap upward into the top and drying the wood with remarkable rapidity, a result more certainly attained in the arid or semi-arid than in the moist and humid regions. By this method the writer has seen fir timber dried out within a few days to a degree sufficient for all practical purposes. Where it is employed in the springtime, when the bark is slippery upon the wood, the log will be peeled perfectly of its bark within a few days, and as this removal of the bark eliminates one of the main causes of decay, for the covering absorbs moisture and collects and holds the fungus of dry rot, this period would seem a good time for felling mine timbers when the trees are thus treated. A better period, however, would be during the winter season, when there is a minimum of sap within the tree and the wood is dormant; but the tops should be left with the log that they may draw the sap to themselves in the spring, thereby drying and peeling the timber to a degree.

In the use of timber for support the weight should be resisted as far as possible in line with the grain, for the strength of the timber is materially greater in compression upon the ends of the fibers than transversely across them. Round timber is stronger than that which is sawed or hewn, for such deformation of the original piece cuts the grain of the wood and thereby weakens it. The squared timbers are the more easily shaped and manipulated, and for this reason are in frequent use in underground operations of magnitude.

Because of heat and poor ventilation in underground workings, together sometimes with alternations of dry and damp air, timber supports are subject to rapid decay, which is evidenced by a growth of fungus and a softening or weakening of the wood-fibers. Good ventilation is a necessity to the preservation of timber in such places although similar results are accomplished artificially. Water trickling down the wood tends to wash off the fungus spores and thus acts as a preservative, but in many places this method is impossible of application, and other means to the end are required. In underground operations, and especially

among the mines, the simple question of the preservation of the timber supports against decay is not the only principle involved, but the workings and the timber contained therein should be preserved against fires which have proven so disastrous to mining. Some preservative therefore should be employed that will render timber proof not only to rot but against fire as well, and such results are obtained by the processes using metallic salts, of which zinc chloride has proven to be a cheap and effective antiseptic and is the one most frequently employed. The methods in use are those of steeping the timber for a time in a bath of the solution or, as is generally now done, of forcing the materials into the cells of the wood by hydraulic pressure applied in a closed vessel containing the pieces.

#### SCIENCE OF SUPPORT.

Invariably in the support of earthworks the primary consideration is that of safety: first for humanitarian reasons, as regards the lives and persons of individuals; and second, for economic reasons, that the workings may be kept open in order to carry out properly the purposes for which they are constructed. Economy should always be sought after, but it is necessary to differentiate between the true and the false economy in carrying out the operations. Preliminary training of a practical nature is an indispensable part of the equipment of the successful operator, to whom not only a general but local experience as well is of large importance; for it is only by actual knowledge in the handling of affairs that he is enabled to judge correctly of the conditions and to apply the proper remedies for overcoming the difficulties that are continually arising. The physical characteristics of the formations in and through which earth-workings are driven determine the methods of procedure, as do also movements of the rock-masses. The general conditions of the formations determine the general plan of procedure, as also do the size and character of the workings themselves, while local conditions determine local and detailed methods of procedure.

All pressure affecting earthworks is due to natural forces, of which gravity acting vertically downward is the fundamental consideration. Indeed it is a fact that all pressures met and to be resisted in earth-workings are intimately connected with and are really a part of the action of the force of gravity. The pressure-forces encountered in underground excavations are due to the resistances offered by the rock-masses to the force of gravity, and they are measured both in amount and direction by the resultants between gravity and the resistances thereto. When gravity is equaled in amount by and opposed in direction to the resultant of the resistances to gravity, which includes not only the resistances offered by the rock-masses themselves but those furnished by the application of natural and artificial supports, then do we have a condition of stable equilibrium wherein a state of rest is existent. When, however, these forces are unequal in amount or where their directions are divergent, then do we have a condition of unstable equilibrium with its consequent movement.

The support of earthworks in general, however, deals with so many uncertainties that it rarely becomes an exact science, and usually it is far less capable of mathematical treatment than is engineering construction, wherein a structure is

dependent not only upon the strength of the materials entering into it, which usually varies even in the same material, but upon an assumed factor of safety that is sometimes also called a factor of ignorance. In applying support to earth-workings the measure of the pressure-forces and their direction as well, is usually indefinite, for both are affected by so many varying and unknown conditions that the application of principles becomes often a matter of judgment, experimentation and renewal.

#### FUNDAMENTAL SUPPORTS.

The usual supports for particular workings are: for level workings, including passageways and stations, the single piece, the half, three-quarter and full set, either as a square-set or with inclined uprights, the arched and the saddleback set, together with the arch and the pillar. Distance pieces, where necessary, retain the sets in their proper relative positions, longitudinally; for inclined and vertical rectangular passageways, including shafts and the interior workings known as raises and winzes, the usual pieces are the wall-plates, the center-plates and the posts, located as square-sets, together with the close-cribbed plates either of round or squared timber, and the lighter cribbed planking; for vertical round and elliptical shafts, the tubbing of stone, brick, cast iron and wood, together with their bearing rings; and for extraction places, props, and stulls, the half, three-quarter and full sets, the posts, caps, girts, cap-sills, sill-girts, and the single and double-post sill, of the square-set framing, together with pens and bulkheads.

Of parts of general utility to earth-workings there might be named the blocks and wedges wherewith supports are held firmly in their proper positions; the lagging and spiling, pole, split and plank, for the close or tight and open or loose lining of the workings in both normal and abnormal ground; the single piece, half, three-quarter and full set, the arch and saddleback, together with the crib and pen and bulkhead, for reinforcing supports; and of special parts of general utility there might be named the false timbers and sets that are used to keep the workings open during the placing and replacing of supports, together with those single pieces and other parts that are variously applied in connection with supports.

The shaping of all timber for support is done by the use in some form of the tenon and mortise and the miter, either singly or in combination; and these are fundamental joints however much they may vary in practical detail, as hitches and shoulders, squared and beveled, the joints giving inclination to the parts, gains, grooves, and the various other contrivances in use for enabling the timbers to come together from two or more directions and to connect properly at the joints. In framing supports for particular work the joints should be planned to resist in the strongest manner possible the pressures bearing upon the timbers and especially where such pressures are abnormal, but the information necessary to determine such points may be a matter of previous knowledge or it may be a problem for experiment, to be developed only through the failure of the earlier supports.

Where the framing of timbers for support is a matter of the utmost precision, as in the shaping of supports for rectangular inclined and vertical shafts, all

measures and the marks for cutting are taken either from a particular face of a piece, often in such cases from what will be its top when in position, or, preferably, the marks and measures are taken from a center or datum-line along the center of that which will be the inner face of the timber when located in position, the truest face being always the one selected. The upright lines are thereafter marked at right angles to this datum-line, while those across the timber, from its inner to its outer face, are taken at right angles to the selected inner face. By this method the frames can be so exactly dimensioned that the bottom of a deep shaft will be of exactly the same interior cross-section as is the top or collar.

Both square-sawed and round timbers are sometimes framed by machinery, especially the parts for the square-sets employed in extraction places, but round timbers for the level workings are almost invariably shaped by hand. These are marked by a center or datum-line from end to end, usually by the chalk-twine, and the line across one end of the piece is taken from that end of the datum-line through the center of the timber, its corresponding line across the opposite end being located by sighting a short straight-edge upon the edge of a second straight-edge, the edge of which coincides with the end cross line first marked off. All other lines are measured and marked off at right or desired angles from the above center and cross lines, they being located usually at either end of a timber by means similar to those above mentioned with the idea of bringing all faces and shoulders to correspond exactly with desired planes and angles, that the joint-parts may truly come together when the timbers shall have been placed in their proper positions.

#### **SUPPORT OF EARTHWORKS.**

In the support of surface earthworks, as embankments, walls, trenches and open-cuts, and quarries, the materials of which they are constructed or in and through which they are driven, furnish the only supports required when such materials are of themselves of strength and texture sufficient to support the workings.

An embankment, *per se*, is constructed of indifferently sized materials heaped together to form a bank or mound and dependent for its integrity upon the friction between the different particles of which it is composed. Such a structure made up of various earthy materials, soil, gravel, and crushed and broken stone, will retain its form when the friction between the different particles and, in a lesser degree, the texture of the particles themselves are equal to or of greater moment than is the force of gravity, the weight, which causes them to seek a lower level. This ratio between weight and combined friction and texture is known as the natural slope or angle of repose, and experiment has fixed its value for different materials. When, owing to compression or other causes, the tenacity between the particles themselves increases in amount above that due to friction, then does the natural slope become steeper and the bank partakes more of the nature of a wall. When the tenacity between the particles, or in other words the texture of the materials of construction, becomes possessed of sufficient strength to withstand the weight-pressure to be supported, then the angle of the natural slope may become vertical and the structure becomes a wall that is dependent for its stability upon the strength and mass of its materials of construction.

Walls may be formed of the natural earthy materials or built up by artificial methods. Embankments are often supported by walls of earthy, metal or timber construction, which are then known as "retaining walls."

Trenches and open-cuts are supported either by the natural materials of which their sides are composed, depending either upon the friction between the particles thereof or upon the strength of such materials, and by artificial supports as well. For permanent supports retaining walls built up of earthy materials are usually employed, while for temporary use timber is available, the side materials being retained in position by beams and struts abutting against either wall of the excavation. When the materials composing the sides are unstable and liable to fall away then timber framework, supported by the struts against the walls, is employed, and where the material is too soft for the usual methods of support forepoling or spiling is used.

In quarries, the walls and extraction places are supported either by the natural slope of the ground or the work is done in benches in manner similar to that employed in the underhand stoping of underground workings. These benches may be carried with the line of natural slope of the materials, but their line should never be advanced at a steeper angle.

In underground earthworks the level workings, including passageways and stations, are supported by earthy materials in the form of the natural rock sides and back, as pillars, irregular, round or rectangular, gangway or chain pillars, panel pillars and stump pillars, and by pillar-arches. Artificially the level workings are supported by earthy materials, as stone in blocks, broken and crushed (as masonry, dry and wet, in walls, arches and stulls, and as waste-filling and waste-stowing), brick (masonry, wet, in walls, arches and pillars), and cement (in walls, arches and pillars, or applied as a thin coating in successive layers); by metallic supports, in which the single piece, the half, three-quarter and full sets, and all parts thereof, the arched, the cylindrical and the oval workings are formed of structural iron and steel plates and beams; by timber, of which the single piece, the half, three-quarter and full sets, the arched and saddleback sets, are framed as special parts for specific purposes; and by combination supports, as of earthy materials and metal or timber and of metal and timber.

Of the inclined and vertical passageways the inclined shaft, of one, two, three and four compartments, is supported by the earthy materials in the form of the natural rock in place and, locally, as side pillars. Artificially the inclined shaft is supported by stone, brick and cement, walls and pillars, with or without cap-plates; by wall-plates, centers and posts of structural iron and steel; and by timber supports in the form of wall-plates, center-plates, posts, cap- and sill-plates, and as girts, with all parts framed, located and aligned with exactness.

The vertical round and elliptical shafts are supported by the earthy materials in the form of the natural rock in place, and artificially by stone, brick and timber tubbing, with bearing rings and exterior coffering.

The vertical rectangular shafts, single and double width, of one, two, three, four, five, and six compartments, are supported by the natural rock in place, in which case framing is often put in for the purpose of carrying the guides for cages and skips; and artificially by metallic supports in the form of wall-plates,

centers, and posts of structural iron and steel, and by timber supports in the form of buntons, wall-plates, center-plates, and posts, with all parts framed, located and aligned with exactness.

Raises and winzes, which are the interior workings passing from level to level, usually within the deposits containing materials of economic value, are often supported by timber frames similar to those of the inclined and vertical rectangular shafts, but sometimes the supports of these workings are made a part of the usual framing of the extraction places within which they frequently form passageways.

Of extraction places, the horizontal deposits are supported by earthy materials in the form of the natural rock in place, as pillars (irregular, round or rectangular, shaft and gangway pillars, panel and boundary pillars), and as pillar-arches. Artificially such deposits are supported by the earthy materials as stone in blocks, broken and crushed (masonry, dry and wet, in the form of walls, pillars, in pens and stulls, and as waste-filling and waste-stowing; brick (masonry, wet, as pillars and arches and walls), and cement as walls and pillars; metallic supports in the shapes of hollow cast cylinders of iron and steel and certain structural beams that may be used as props; timber supports, wherein round timbers are employed for use as props and are likewise used in crib and pen, squared timbers being also used in the open pen; and combination supports, in which waste-filling and stowing is used in connection with the timber pen.

Within the inclined and vertical deposits and masses, as regards the earthy materials, the natural supports to the roof and sides and to the hanging- and foot-walls are furnished by the natural rock in place, either that of the exterior rock or that composing the deposits that is left in position in the shape of pillars of various dimensions and forms, the artificial earthy supports being those earthy materials that are employed as waste-filling and waste-stowing within the open places. Timber furnishes the greater part of the artificial supports in the extraction places of the inclined and vertical deposits and masses, wherein it is used in various forms. The stull is but the adaptation of the prop to the uses of the inclined and vertical deposits, and similarly its province is to support the weight of the hanging-wall upon the foot-wall. In steeply inclined deposits, where either the hanging- or foot-wall is weak and inclined to fall away without intermediate support, a post is often placed beneath the stull to hold it in place and to support intervening ground between two stulls, the post being supported at the other extremity upon the stull beneath, thus forming the three-piece or three-quarter set, the full or four-piece set being a similar adaptation of the stull with supporting posts beneath either end to the set frame within the extraction places and employed when the rock of both walls is of too weak a nature to stand without such support.

A still further development of the set to the uses of supporting the extraction places brings us to the square-set, now so generally employed among the metal mines for the support of wide veins and the irregular mass deposits. Here the system applies the unit to the support of excavations, and this unit consists of the single square set, the parts being so framed that the set may be placed in position wheresoever it may be needed, either singly and alone or in combinations large

or small and in any direction, dropping the units in following upward with the hanging-wall of the deposit or in leaving a pillar in position in barren ground, and adding units laterally with the inclination or dip of the foot-wall, the system expanding laterally, longitudinally and vertically with the excavations as desired. These units consist of hollow blocks or squares made up of framed pieces of timber of desired dimensions, those upon the bottom or sill floor being made up of single- and double-post sills, sill-girts, posts, caps and girts, while the units or sets upon the floors above are composed of posts, caps and girts, the cap and girt of the set on the floor beneath forming the sill timbers of the upper sets. In following upward along the foot-wall and as a means of adding units exterior to the system laterally a combination of sill and cap, called the cap-sill, is employed, which is usually supported upon the solid material of the wall and which in turn supports the units above. Almost invariably the units of the square-set system are vertically placed within the deposits, but there are instances where the placing of the timbers at an inclination and along the line of dip of the vein has been successfully done and possibly more satisfactorily than the vertical method would work to the desired end because of the characteristics of the deposit. Cribbed pens and bulkheads are sometimes constructed within the extraction places, and they are often invaluable as a means of supporting the rock overhead.

The combination supports as applied to these classes of deposits comprise the use of timber and the earthy materials, especially the broken, crushed and disintegrated stone that is employed as waste-filling and waste-stowing and which is filled in or built up simultaneously with or subsequent to the processes of locating in place the timber systems.

#### SPECIAL EQUIPMENT.

The surface equipments for level workings are the portals for adits and tunnels; and for inclined and vertical workings, the collar or top arrangements of vertical and inclined shafts, the tower-sills, for supporting the upper sets of vertical rectangular shafts in loose material until firm ground is reached with the supports, and the methods of locating the shaft collars to any desired height above the level of the surrounding plain, either by the regular shaft framing or by the more substantially built up cribbed frame that is filled and rendered solid by waste and broken stone.

The underground equipment consists of: for the level workings, the gates and gateways of chutes for the loading of cars in the passageways, and for stations it consists of the rooms for the location of pumping plants, the sump-tanks and lodges for collecting water at the various levels, and the port ropeways above for the purpose of giving added height to shieve-wheels within the shafts for sinking purposes; for inclined and vertical passageways, of shafts, the guides of timber and of rope for carrying and holding in proper position therein the cages and skips and buckets, the pentice of natural rock and of timber bulkheads within the shaft for the protection of the men engaged in sinking, the timbers and iron plates for protecting the shaft supports during the blasting of hard rock in sinking, and the hanging bolts for retaining the shaft sets in position during the processes of locating and blocking them in place; for the extraction places, the methods

-filling above the drifts by drift sets and by stulls, and in the the methods of constructing bends and turnouts in the drifts s by swing-girt, by turning-sheet, by enlarged junction-set size above, by angle-braced support over the drift, and by the at sets, and the methods employed for making connections between narrow and in wide deposits and of supporting the waste-filling ing the process; and as regards the question of special equipment there methods of underground storage by ore and waste chutes, by ore bins, storing waste rock in the shaft during sinking.

#### MANIPULATION OF SUPPORTS.

As regards the handling of supports and their transportation underground there are the methods commonly employed in the horizontal workings, in the level passageways and extraction places; and in the inclined and vertical workings, the methods used in shafts and in raises and winzes and those employed within the extraction places of deposits.

As regards the locating and aligning of supports: in connection with the level workings there are the ordinary methods of procedure in normal ground and the special methods employed in soft and heavy and in running ground, both in passageways and stations; in connection with inclined and vertical shafts of all shapes and sizes there are the ordinary methods of procedure for locating and aligning the parts in normal ground and the special methods employed in soft and heavy and in running ground; and in connection with extraction places there are the methods of locating the props and stulls, of building up the cribs and pens, of placing the sets, and the ordinary and the special methods of procedure in building up the square-set units to suit the demands of the occasion, dependent upon the normal and abnormal characteristics of the ground.

As regards the reinforcing of supports: in connection with the level workings, for both passageways and stations there are the inner reinforcing sets, the doubling-up sets, the inner and exterior saddleback and arch, and the exterior pieces, as caps and posts; in connection with inclined and vertical shafts there are the exterior plates and the bulkhead plates; and in connection with extraction places, for horizontal deposits there are the prop batteries, for inclined and vertical deposits there are the wall-posts with stull and stull batteries, and for wide veins and mass deposits in connection with square-sets there are the three-quarter and full reinforcing sets, angle-braces variously applied, the combination of reinforcing set and angle-brace variously applied, the brick-work bulkhead and the solid bulkhead.

As regards the easing and relieving of supports, in heavy and in swelling ground: in connection with the level workings, for passageways the exterior easing-cap and post with strut and used with open lagging, the exterior-triangle easing set with open lagging, the spreading-post set with open lagging, and for stations, the exterior cap and post with struts and open lagging, and the exterior saddleback with open lagging; and in connection with inclined and vertical shafts, for inclined shafts there are the exterior cap-plate and the exterior post-plate

with struts, and for vertical rectangular shafts there are the exterior stringer casing-sets and the exterior wall-plate easing-sets.

As regards the repairing and replacing of supports: in connection with level workings, there are the methods employed to support the ground during the operations, those used in removing the old supports and in placing the new supports in position; in connection with inclined and vertical shafts, there are the methods employed in supporting the ground during the operations and those used in removing the old supports and in placing the new supports in position, the methods of bringing the shaft into alignment and the wall-plates to their proper relative positions, horizontally or otherwise, and the methods of handling caved ground in the vicinity of shafts; and in connection with extraction places there are the methods to be employed in recovering lost and caved ground.

## ALLOYS AS SOLUTIONS.<sup>1</sup>

BY JOHN ALEXANDER MATHEWS.

FOR a student either of metallurgy or history, it is not necessary to adduce evidence to show that the knowledge of how to extract metals and to fit them for use is of great antiquity. The people living long before the Christian era knew that mixed metals often possessed properties very different from those of the constituent metals, and they applied this empirical knowledge to the reduction of metals from their ores and to the production of alloys from the metals thus obtained. Nevertheless a knowledge of the molecular constitution of these substances was lacking until within a very few years, and if any of the scientists of even as late a day as the first half of the last century had any conception of the truth in regard to alloys, the means of experimentally confirming their speculations had not yet been evolved. But had the means been available, it could not be expected that the difficult problems of molecular physics, which a study of alloys involves, would have been solved until a molecular theory of the constitution of all matter had been enunciated, nor could it have made any progress before the period of chemical reform begun by Lavoisier, the period of quantitative investigation. But only recently, even in this period in which we still labor, have the relations of physical properties to chemical constitution attracted both chemists and physicists to concerted activity, and in this field of investigation alloys were slow to yield fruitful results. Physical and chemical methods of research, which were entirely satisfactory when applied to bodies of other kinds, failed utterly to afford a rational explanation of the molecular conditions existing in alloys. The solution of these problems required new methods and new apparatus. Fortunately, these are at hand; they have been slowly evolving and the past decade has been most fruitful of results.

With few exceptions, the great leaders in this new branch of applied science belong to the contemporary school of English and French physicists and metallurgists, a résumé of whose achievements is given in the pages that follow.

A most potent factor in this recent progress has been the official recognition of the necessity of study along these lines. More than 10 years ago the Institution of Mechanical Engineers of Great Britain appointed an Alloys Research

---

<sup>1</sup> Reprinted with some modifications from the *Engineering and Mining Journal*, Dec. 21 and 28, 1901.

Committee, which receives financial assistance from the institution; five reports have been published by it, and a sixth report is, I believe, about to appear. It is in connection with the work of this committee that Sir William Roberts-Austen, his pupils and the co-workers of his staff have produced such excellent work, especially in pyrometry and in explaining the complicated changes, allotropic and otherwise, which steel and cast iron undergo.

The practical operations of annealing, tempering, hardening, etc., can now be conducted upon a scientific and rational basis. The effects of thermal operations can be predicted accurately and desired results obtained unfailingly. It would be too much to say that all this is due to this committee alone; but if we include also the committee of the British Association, appointed to investigate the nature of alloys, of which Mr. Neville is chairman, and the "Commission des Alliages," of the Société d'Encouragement l'Industrie Nationale, as also sharing the honors of recent great advances in both our theoretical and practical knowledge of alloys, then we have recognized the three most prolific contributors to our knowledge of metallic mixtures. While giving these official bodies full credit for their discoveries, we would not detract in any way from the honor due to many individual workers not connected with committees who are scattered through many lands. It is safe to say, however, that the larger results of the concerted work of committees has had a stimulating effect upon the private worker. One of the greatest evidences of appreciation of the necessity for research in connection with alloys is that nearly every railroad in France and many metallurgical concerns contributed to sustain the work of the "Commission des Alliages."

The purely scientific reasons which have made possible the recent advances in alloys research seem to me to be: (1) *An increased knowledge of solutions.* For this we are undoubtedly indebted in very great measure to the great Dutch and German physical chemists—Van't Hoff, Roozeboom, Ostwald, Nernst and others. (2) *The development of metallography.* This seems to have originated with Dr. Sorby, of Sheffield. Although he wrote about the microstructure of meteoric iron as early as 1864, the progress of metallography was very slow. Only within the past 10 or 15 years have even metallurgists begun to recognize what a valuable aid to research it is and unfortunately the manufacturers have not yet given it just recognition. Recent progress in this branch of applied science is most closely attached to the names of Stead, Martens, Osmond, Le Chatelier, Charpy, Roberts-Austen, Howe and Sauveur. (3) *Improvements in pyrometry.* The study of metals, alloys, furnace reactions, etc., was retarded for many years because of the lack of the suitable means of measuring accurately very high temperatures. Such means as have been available for these purposes in past years were not suitable for general use around shops and metallurgical works and were inconvenient even for the laboratory. Now, however, there are at least two reliable pyrometers which are conveniently manipulated and lend themselves readily to accurate measurements of high temperatures. The Siemens electrical resistance pyrometer, as perfected by Callendar and Griffiths, gives wonderfully accurate readings within certain limits. For use both in the laboratory and in the factory it does not seem as popular—in the United States at least—as the Le Chatelier thermo-electric

couple. The very accurate work of Messrs. Heycock and Neville is perhaps as good a recommendation for the possibilities of the electrical resistance pyrometer as can be cited. The particular advantages of the thermo-electric couple as applied to alloys research are—its accuracy at high temperatures, its ability to be used with very small masses of heated substances, and, indirectly, its ability to be used in conjunction with a photo-autographic recorder, as has been so well demonstrated by Sir William Roberts-Austen.

*Crystalline Growth in Metals.*—Before entering upon the consideration of alloys, it may be well to note a few general properties of metals, particularly their mode of crystalline growth and the effects of strain. To both of these subjects Prof. Ewing and Mr. Rosenhain have given much attention and have explained the phenomena of these operations very clearly. They state that all solid metals are crystalline, even though when examined by the microscope the individual crystals or crystalline grains may not present a simple geometrical outline. The essential point is that the particles composing the mass of a crystal lie in one direction, *i.e.*, have the same plane of orientation. Mr. G. T. Beilby read a paper at the meeting of the British Association held in Glasgow, September, 1901, upon "The Minute Structure of Metals," and cites evidence to show that he has identified minute spicules or scales showing remarkable uniformity of size and appearance in metals of all the leading groups. These under mechanical treatment may be converted into transparent glass-like substance and may again reappear as spicules unchanged in size. The diameter of the scales is estimated to range from 1-300 to 1-400 of a millimeter. The metals examined by Mr. Beilby include gold, silver, platinum, cobalt, nickel, chromium, iron, copper, lead, bismuth, antimony, tin, cadmium, magnesium, aluminum, zinc, and sodium. Brasses and bronzes were also examined. The author says that the crystalline faces and cleavages of such metals as antimony, bismuth and zinc exhibit the same features as the softer and more malleable metals, being covered with a film of transparent metal, while in fractures at right angles to cleavage planes, scales are distinctly seen. Mr. Beilby's conclusions are: "The persistence of these minute scales or spicules under all kinds of mechanical and thermal treatment, the remarkable uniformity of their size and appearance in metals of all the leading groups, their disappearance into the transparent form and their reappearance again, apparently unchanged in size or otherwise, seem to afford fair ground for the conjecture that they are in some way definite units in the structure of metals."

It may be that these are the "units" whose arrangement in certain definite orders constitutes crystals, and this similarity of disposition of particles is what constitutes orientation. Prof. Ewing explains crystallization in metals in this way: the formation of crystals must be assumed to start simultaneously at many points. The crystals grow until they touch one another, and, although individual crystals are similar, it is not necessary that the corresponding axes of any two of them lie in the same plane. No doubt each crystal is of perfect form so long as it is free to grow in all directions; when the crystals touch, their symmetrical growth is hindered, but the orientation of the subsequent particles which attach

themselves is not changed. It is for this reason that orientation<sup>2</sup> rather than geometrical outline is considered the essential feature of crystalline growth. In the case of commercial metals, more or less impure, the impurities are cast out by the growing crystals, and being in fact alloys of the admixed metals with the still fluid principal metal, they have a lower melting point than the pure metal. Therefore, they solidify last and form an investing cement which holds together the primary crystals.

*The Effect of Strain.*—When a polished metal is subjected to strain there is no change noticeable until the stress exceeds the elastic limit. When, however, the plastic stage is reached, there will appear dark lines more or less perpendicular to the direction of stress. This, Prof. Ewing<sup>3</sup> says is not due to fissuring, for by changing the direction of the rays which illuminate the specimen under observation from vertical to oblique, it will be seen that the erstwhile dark lines appear light, while the background has changed from light to dark. Fissures would not have reflected light in any case; the permanent elongation is due to slipping of the components of the crystals past each other. That is, the surface which was originally plain, presents, after stress has been applied beyond the elastic limit, the appearance of minute steps. It is as though one should take a pack of playing cards with their ends presenting a smooth surface. Now if the thickness of the pack of cards were one inch, and the pack were bent, the end surface of the pack would measure more than an inch and would consist of little steps, not only the ends, but also a part of the flat surfaces of the cards being exposed.

In the case of metals, the slip-lines need not necessarily lie in one plane. As many as four sets of parallel slip-lines have been noticed by Prof. Ewing. Mr. William Campbell worked upon this phenomenon independently at about the time that Prof. Ewing was making his preliminary observations. He experimented with tin, while Prof. Ewing worked chiefly with lead, and it is interesting to note how completely their results agree.

The growth of crystals from a solidifying molten mass is easy to comprehend, but why is it that crystals grow in a solid mass of metal not only by annealing but even at ordinary temperatures? Big crystals actually consume the little ones. A bit of rolled tin which was allowed to stand for eighteen months at ordinary temperatures in the laboratory showed a marked change in appearance, due to growth of its crystals. If a specimen of tin is put upon a hot plate and heated to, say, 200°C. for ten days, a growth such as is shown in Fig. 1 is obtained, which shows the tin before and after annealing. This photograph is one of Mr. Campbell's, and is a little under actual size. It also shows very well the different orientation of the crystals. In fact, the growth of these crystals was so rapid that a micro-section through them reveals slip-lines, probably due to this rapid growth. The fact that the slip-lines are only parallel within the same crystal seems to confirm this view, for, had the stress been applied longitudinally by artificial means all the slip-lines would have been more or less normal to the direction of the stress.

Slip Lines in Steel Resulting from Strain.

Fig. 10. 20% Sb, 80% Al  $\times 33$  diameters, oblique illumination, shows crystals of Sb Al in granular ground mass of nearly pure Al.

Fig. 11 50% Sb, 50% Al  $\times 33$  diameters, oblique. Crystals of Sb Al increasing in size and amount, ground mass decreasing.

Fig. 13. 85% Sb, 15% Al  $\times 33$  diameters, vertical illumination. We have passed the summit of the curve; the ground mass of aluminum has disappeared, and some free antimony is seen.

12. 82% Sb, 18% Al  $\times 16$  diameters, vertical illumination. This photograph shows pure Sb Al.

Fig. 14. 95% Sb, 5% Al  $\times 33$  diameters, oblique. Sb Al crystals diminishing in quantity, and ground mass of Sb—probably containing a little Sb Al in solid solution—is conspicuous.

With regard to the growth of crystals in strained metals when they are subsequently warmed, Mr. Rosenhain has offered this explanation: In strained metals the layer of enveloping alloy surrounding the separate crystals becomes broken, and the difference of potential between the metal and the alloy set up by electrolytic action causes a solution of the crystal on one side of the alloy and a deposit on the adjoining side. This he verified by the following experiment: Two pieces of lead were scraped clean and welded by the application of great pressure. A micro-section through the weld showed that the crystals in neither piece extended across the weld. When, however, between two such surfaces a little powdered tin was sprinkled and pressure applied, a micro-section revealed that electrolytic action had taken place and that crystals from either side extended across the weld. Ingenious as is this explanation, yet I am not certain that the proof is conclusive. If I mistake not, at the last Cantor lectures before the Society of Arts,<sup>4</sup> Roberts-Austen and Rose showed crystals of gold extending across a weld, although the purest standard gold was used in the experiment. In fact long annealing of this gold obliterated the weld almost completely.

The effect of strain is very beautifully shown in the accompanying figures.<sup>5</sup> A piece of very pure steel—0.035% C—was bent double in the cold. The magnet-shaped bar was then sectioned through the middle, parallel to the plane of bending. Upon polishing and etching it was seen that the ferrite (pure iron) crystals on the inside of the bend showed the effects of compression. The crystals upon the outer edge being under great tension were stretched, while the crystals near the center, or so-called neutral area, were practically unchanged in shape, although slip-lines may be faintly discerned running through them. Figs. 1A, 1B, and 1C show these three conditions, but the slip-lines are much better shown in Fig. 1D, which represents the neutral area of a similar rod of 5% nickel steel (0.2% C). The slip-lines traversing the large grains of ferrite containing nickel and the surrounding pearlite are plainly shown.

*Freezing Point of Metals.*—With water and many other liquids we know that it is quite possible to lower the temperature to a considerable amount below their freezing-point without the separation of any solid. On the other hand, it is not known that any solid may be heated above its melting-point without becoming a liquid. The property first mentioned is known as surfusion. On account of this phenomenon it would be theoretically preferable to determine the melting rather than the freezing-point of metals, but practically this is a very difficult task, while freezing-points are in most cases easily determined and surfusion need not interfere with their accuracy in the least, for when solid matter begins to separate from a pure liquid thus cooled, the temperature rises rapidly to the true freezing-point and remains constant until the whole mass is solid. Sir William Roberts-Austen cites an instance in which tin was cooled 20°C. below its freezing point without solidification, and I have frequently observed the same result in tin and some other metals: antimony is especially apt to show surfusion. I have repeatedly observed antimony show thirty-five degrees of surfusion, i.e., the

<sup>4</sup> *Journal of the Society of Arts*, 1901, p. 851.

<sup>5</sup> Mathews, *Journal of the Iron and Steel Institute*, Vol. I., 1902.

metal, still molten below  $600^{\circ}\text{C}.$ , suddenly becomes heated again to  $632^{\circ}\text{C}.$ , and remains at that temperature until completely solid.

In working with metals the first point at which solids separate is taken as the freezing-point, and surfusion need not obscure this point, particularly if an autographic record of the cooling curve is taken. If we plot a typical cooling curve of a pure metal, using temperature and time as the co-ordinates, we obtain a curve represented by  $AB$ , Fig. 2, having two very distinct angles, while a portion is horizontal, *i.e.*, the temperature remains constant during the whole period of solidification. If surfusion takes place, and it is more common in pure metals than in alloys, the curve  $A'B'$  represents what happens. The temperature falls below the real freezing-point, and then rises abruptly to that point and remains constant as in  $AB$  until solidification is complete. In impure metals—and since the impurities are usually metallic, they are really alloys—the temperature does

not remain constant at all, but a decided change in direction is noticed indicating the point at which solidification commences as shown in  $A''B''$ . The greater the amount of impurity, the more rounded will appear the cooling curve. Since these are really the curves of alloys and solid solutions, they will be explained at greater length subsequently. This third type,  $A''B''$  is introduced here because it shows that the nature of the cooling curve gives us a clue as to the purity of the metal under examination. To explain surfusion, we need only remember that fusion is always attended by absorption of heat and solidification by evolution of heat. When a "surfused" substance begins to solidify it disengages heat and the temperature rises until the melting-point is reached. No further rise takes place because at this temperature only, liquid and solid are in equilibrium. Any further change of liquid to solid or solid to liquid must be effected by abstracting or adding heat. In practice, either heat is lost

by radiation and the whole mass solidifies, or is supplied by artificial warming, and the whole mass becomes liquid.

*Binary Alloys.*—Having now noted some of the properties of pure metals we may next consider what happens when two metals are melted together. We shall not at this time consider ternary or more complex alloys. The first thing noticed upon melting together two metals is that (1) they mix in all proportions, or (2) they do not. In the first instance, under proper conditions an approximately homogeneous solid mass is likely to result when the molten alloy is cooled. In the second case, on cooling it will be found that the metals have separated into layers, the lighter metal on top. Each layer, however, will be found upon analysis to contain a certain amount of the other metal in solution, just as ether and water dissolve small quantities each of the other. As between certain metals and solid non-metallic elements it seems as though they were absolutely insoluble in one another at ordinary temperatures, although they may be quite soluble at high temperatures. For example, M. Moissan tells us that metals of the platinum group readily dissolve several per cent. of carbon at the temperature of the electric furnace, but cast it *all* out as graphite on cooling. It has not yet been determined whether the graphite, which separates in cast iron, contains iron or not. It seems to me that we shall come nearer the truth if we consider such cases as solutions of almost infinite dilution, rather than as absolutely pure metal or non-metal.

We have just spoken of metals dissolving metals, and it is this conception of alloys as solutions—solid solutions—that has been steadily progressing in favor in recent years and which we hope both to explain and to confirm by citing the results of the experiments of many investigators. Very striking analogies exist between ordinary solutions and alloys; in fact, to point out these similarities is to give our present conception of the constitution of alloys.

*Solid Solutions.*—This expression is due to Van't Hoff, but Roberts-Austen has done most to make it familiar to metallurgists. Our text-books upon physical chemistry contain much information upon the subjects of solutions of gases in liquids, liquids in liquids, and solids in liquids, but are for the most part silent upon the subject of the solutions of solids in solids. The extension of our knowledge upon this subject is very recent and mostly confined to technical periodical literature of recent dates. Prof. Roozeboom and his pupils have carried on researches upon the nature of fused mixtures of salts and their behavior upon cooling. This work throws considerable light upon the problems of chemical equilibrium in alloys. As defined by Sir William Roberts-Austen a solid solution is "a homogeneous mixture of two or more substances in the solid state." In metals no one has worked as yet with non-crystalline mixtures, and solid solutions of metals when crystalline are solid "isomorphous mixtures," or "mixed crystals." The use of these three terms to denote one condition is confusing and unnecessary, and as objections exist to the last two synonyms, their use should be discontinued. The term "mixed crystals" is particularly apt to convey a wrong impression to one who sees this name for the first time, especially if it is unaccompanied by a definition or explanation.

Mr. Stead, in the *Journal of the Iron and Steel Institute*, 1900, classifies solid solutions as follows:—

- (1) Those in which one constituent of an alloy in crystallizing retains a portion of the other homogeneously diffused through its whole crystalline mass.
- (2) Those in which during crystallization the central portion of the crystals contains less of the dissolved substance than their external boundaries.
- (3) Those in which the metals form a definite compound, which is retained in solid solution in the excess of metal or metals. I should like to add that the "compound" may be the "solvent," in the sense in which those terms are here used.

The condition described in (2) is that of an unstable system. Crystallization has taken place more rapidly than diffusion, and in such cases where crystals are not of uniform composition from center to outside complete homogeneity could probably be obtained by annealing. Mr. Stead adds a fourth class. (4) Those in which the non-metallic elements form definite compounds with a portion

of the dissolving metal that remains in solid solution. This class would include the property of metals, such as iron and copper, to dissolve a portion of their oxides. Such solutions have been little studied, but E. Heyn<sup>6</sup> finds that the fusibility curve for solutions of cuprous oxide in copper is of the type of the freezing point curve of salt and water and shows a eutectic.

In the case of metals which do not mix in all proportions, the two layers formed on cooling consist of solid solutions belonging to one of the types just mentioned. Some of the pairs of metals which do not mix in all proportions at ordinary temperatures are Zn-Pb, Zn-Bi, Pb-Al, Bi-Al, Cd-Al. These have all been studied by Dr. Alder Wright,<sup>7</sup> and Mr. Campbell<sup>8</sup> and myself have repeated and verified a part of Dr. Wright's work upon the aluminum alloys. In all these pairs of metals the relative solubility is a function of the temperature; therefore, it appears likely that at some temperature solubility is complete. Accordingly we may represent the condition existing between these and any other similar pairs of metals by a "critical curve" (Fig. 3). A and B are the metals

<sup>6</sup> *Bulletin de la Société d'Encouragement de l'Industrie Nationale*, 1911 (2), p. 276.

<sup>7</sup> *Proceedings of the Royal Society*, 1889-1893.

<sup>8</sup> "The Alloys of Aluminum." *Journal of the American Chemical Society*, 1902, p. 253.

which are not entirely miscible at ordinary temperatures, but which form layers. The metal *A* contains the quantity of *B* represented by the space  $Ax$  on the composition line. Similarly the metal *B* contains  $By$  per cent. of *A*. With increasing temperature the mutual solubilities increase, and at a temperature *z* there is but one solution. Alloys represented by percentage compositions, which fall outside the curve  $xzy$  are homogeneous. Those whose composition is represented by percentages within  $xzy$  may be considered as similar to emulsions at all temperatures below the curve at which they are liquid. They are incapable of remaining homogeneous. To such alloys, Sir George Gabriel Stokes gives the name of *ideal* (i.e., unreal, imaginary) alloys while those falling outside the area  $xzy$  he calls real alloys. The distinction between such pairs of metals as form separate layers on cooling, and the more or less laminated or striated structure produced upon solidification of eutectic alloys, will be pointed out later.

*Molecular Freedom in Solids.*—It must not be supposed that because certain bodies are designated "solid" that entire absence of molecular mobility is implied. Such an idea is far from the truth; the difference in mobility of the molecules in "solids" and "liquids" is one of degree only. On the boundary between solids and liquids substances are said to be viscous or plastic. Just as crystals of a soluble salt placed in contact with water tend to become dissolved and uniformly distributed throughout the solvent, so metals, even at normal temperatures, tend to form uniform solutions; this tendency, though slight, is none the less real. Metals even tend to evaporate and to be surrounded by their own vapor. Robert Boyle thought that "even gold" had its "little atmosphere." From analogy with salt solutions we may suppose that one metal dissolved in another shows a small expansive tendency to escape from solution; in other words, exhibits osmotic pressure.

Prof. W. Spring, of Liege, demonstrated the fluidity of solids, if I may use that expression, in his famous experiments upon the behavior of metals under exceedingly high pressures—ten thousand atmospheres, more or less. He showed that by pressure alone:—

(1) Metals can be made to flow. The familiar operation of striking coins illustrates this property of metals and alloys. A medal has recently been struck in steel.

(2) Solids, both metals and salts, like liquids and gases, possess perfect elasticity and suffer no permanent diminution in volume by pressure. Strain, torsion or bending may produce permanent deformation in a metal or alloy, but there is no limit of elasticity in regard to diminution in volume, for when the pressure is removed the solid assumes its original volume. An exception to this is cited by Prof. Spring in his next generalization, viz.:—

(3) Allotropic changes may result from pressure. Prismatic sulphur becomes octahedral sulphur and amorphous arsenic becomes crystalline. In both these cases the second allotropic form is denser than the first, and from these and other experiments Prof. Spring argues that allotropic transformations by pressure show that matter takes the state which corresponds to the volume it is obliged to occupy. Moissan's brilliant experiments upon the production of artificial diamonds illustrates this principle.

(4) Metallic filings are converted by pressure alone into solid masses, just as if they had been fused. Similarly mixed filings yield alloys: *e.g.*, brass was produced by compressing clean, flat surfaces of zinc and copper. Reactions of double decomposition between dry salts and the production of the highly colored regulus of Venus ( $\text{Cu}_2\text{Sb}$ ) show that not only intimate agglutination, but also chemical combination may take place between bodies in the solid state. I have confirmed some of Prof. Spring's results, but was unable to produce several typical inter-metallic compounds as  $\text{Au Al}_2$ ,  $\text{Sb Sn}$ ,  $\text{Sn Cu}_4$ , etc.

Prof. Roberts-Austen has demonstrated the fact of molecular mobility among solids in a prolonged series of very beautiful experiments upon the diffusion of gold into lead at temperatures from  $250^\circ\text{C}$ . down to the ordinary temperature. Graham showed long ago that gold diffusing into molten lead, tin, etc., obeyed Fick's law,

$$\frac{d v}{d t} = K \frac{d^2 v}{d x^2}$$

where  $x$  is the distance through which diffusion takes place (against gravity),  $v$  is the concentration of the diffusing metal,  $t$  = time, and  $K$  is the diffusion constant, *i.e.*, the quantity of metal in grams diffusing in unit of area ( $1 \text{ cm}^2$ ) in unit of time (1 day) when unit difference of concentration (in grams per  $\text{cm}^3$ ) is maintained between the sides of a layer 1 cm. thick.<sup>9</sup> That is, metals dissolve in metals, just as salts dissolve in water. Were it not for the operation of this law it would not be such an easy matter to prepare homogeneous alloys. For instance, with relatively little stirring and relying upon diffusion, it is very easy, according to Sir William Roberts-Austen to make 1,200 oz. of coin gold alloy, the first and last pourings of which shall not differ by more than 1-10,000 part in fineness. The idea that interchange of matter can take place between solids is not a new one, as is shown by the cementation process of the ancient Hebrews by which gold was purified.

The experiments upon the diffusion of gold into solid lead, which Roberts-Austen has recently reported to the Royal Society, may be summarized as follows:—

Gold placed in the bottom of a tube filled with lead and maintained at  $250^\circ\text{C}$ . ( $79^\circ$  below the melting point of lead) appeared at the top in notable quantities in a month. At  $100^\circ\text{C}$ . the rate of diffusion was 1-100,000 of that in fluid lead, and in solid lead at the ordinary temperature, allowed to stand in contact for four years, unmistakable signs of diffusion took place, but its rate was such that in one thousand years the diffusion would equal that taking place in one day in lead just molten.

Fig. 4 shows another sort of change which may take place in solid materials. An alloy containing 88.7% Cu and 11.3% Al corresponds closely to the compound  $\text{Cu}_3\text{Al}$ . It should, therefore, appear almost homogeneous, and so it does when quickly cooled. When slowly cooled, however, it changes at  $500^\circ\text{C}$ ., or nearly  $600^\circ$  below its freezing point, and presents the variegated appearance shown in Fig. 4, which no metallographist would care to call a typical structure for an inter-metallic compound.

<sup>9</sup> See Roberts-Austen, Graham Lecture before the Philosophical Society of Glasgow, 1901.

We apply practically the phenomenon of molecular mobility in solids in all annealing operations. By this means the ill effects of strain due to sudden cooling are remedied, and equilibrium is established in articles of metal, glass, enamel and other materials. The rate of diffusion of gold in lead at the various temperatures is an indication of the rapid increase in molecular mobility which results by very moderate increments in temperature. This knowledge is applied whenever we resort to moderately elevated temperatures in all sorts of annealing operations. Steel is very sensibly annealed at temperatures more than 1,000°C. below its melting-point.

*Behavior of Binary Alloys during Cooling from Fused State.*—It has been stated that metals may or may not mix in all proportions. If they do mix, we may further distinguish those cases in which (1) chemical combination does not take place, and (2) those in which chemical combination does take place, and one or more intermetallic compounds result. The reality of the existence of intermetallic compounds is undoubted, yet, so far as I know, no mention is made of them in the standard books on general chemistry. Indeed very little is known in regard to the nature of the affinity between metals. It does not seem necessary to suppose that the laws applying to combinations between elements or radicals which are relatively electro-positive and electro-negative be equally applicable here; and our conceptions of valency are seriously shattered if we attempt to reconcile them to intermetallic compounds. The difficulties in studying intermetallic compounds are very great, because they are troublesome to isolate, and in many of their properties they resemble the metals. Frequently, too, they are quite unstable and show marked dissociation. Chemical methods of studying them are of very limited application; filtering off solidified intermetallic compounds from a still fluid metallic mother liquor at high temperatures presents extreme difficulties and volatilization of the excess of solvent metal is rarely applicable. In a few cases the heat of formation can be determined and electrical methods by which the potential of binary alloys is compared with that of the more positive metal in the alloy may yield important evidence as to the solubility of one metal in another in the solid state. The microscopic evidence and that of the freezing-point curves require some amplification, for they are not wholly satisfactory in this regard. (See Herschkowitz, *Zeitschrift fuer Physikalische Chemie*, Vol. XXVII., p. 113, and Laurie, *Transactions of the Chemical Society* (1888), p. 104.) One great difficulty in studying intermetallic compounds by chemical means is that even if definite crystals can be isolated from an alloy by using suitable solvents it is found that their compositions vary according to the percentage composition of the alloy from which they were obtained. Apparently identical crystals isolated from alloys of different composition, though of the same crystalline form, will usually differ on analysis. In other words, crystals need not be composed solely of a definite intermetallic compound. This seems to have been the general idea, however, in times past and every worker who succeeded in isolating definite crystals from an alloy promptly assigned to them a formula. Unless a compound is indicated by the appearance of a summit in the freezing-point curve, and unless the alloy corresponds in percentage composition exactly to this summit, it is more than likely that the crystals isolated, though

isomorphous with those of the compound, are not of exactly the same composition. This, in general, no doubt accounts for the "discoveries" from time to time of possibly ten Al-Cu compounds and nearly as many Al-Mo compounds of the types  $R_x-R'_y$ , where  $x$  and  $y$  may be any number from one to twenty. To the same category belong the numerous carbides of iron. I have discovered six in the literature,—but not in iron,—the existence of all but one of which is denied. For this very reason, namely, the improbable existence of most of the intermetallic compounds mentioned in technical literature of the past ten years, I hesitate to give the formula,  $WAl_7$ , to some beautiful hexagonal crystals, which are so refractory that neither aqua regia, nor aqua regia and sulphuric acid, nor fused sodium carbonate scarcely attacks them, and whose composition agrees very closely with that formula.<sup>10</sup>

*Cooling Curves.*—During the cooling of a molten alloy, various constituents may crystallize out successively; definite compounds which are stable only at high temperatures may split up into simple constituents; or, new combinations, impossible at high temperatures, may be formed as the temperature falls. All such molecular changes are accompanied by corresponding thermal effects, such as the disengagement or the absorption of heat. By the accurate measurement of the temperature at which these changes take place we obtain most valuable information in regard to the molecular movements in the mass. The Le Chatelier pyrometer used in conjunction with an auto-photographic recording device seems best suited to measure and record these changes. The general principles of thermo-electric pyrometry are too well known to require discussion here. For reference, however, I could not do better than to refer to H. Le Chatelier and O. Boudouard's volume, *Mesure des Températures Elevées*, or to its English translation with supplement by George K. Burgess.

The instruments used by Sir William Roberts-Austen in his private laboratory have been described fully in the *Reports of the Alloys Research Committee* of the Institution of Mechanical Engineers. During several months that it was my privilege to work in his laboratory I made use of a recorder designed by Dr. Stansfield and constructed by the Cambridge Instrument Company. For a description of this, see the *Journal of the Franklin Institute*, January and February, 1902. Neither of these forms of recorder is perfect, and many improvements will be required to produce an instrument that is entirely satisfactory. Fortunately it is not the accuracy of these instruments, but certain inconveniences of manipulation that are at fault. In using any thermo-couple, with or without a recorder, it is necessary to calibrate frequently. The temperatures usually taken as "fixed points" are the boiling points of water ( $100^\circ$ ), naphthaline ( $218^\circ$ ), and sulphur ( $444.5^\circ$ ); the melting points of tin ( $232^\circ$ ), lead ( $329^\circ$ ), aluminum ( $655^\circ$ ), gold ( $1,061^\circ$ ), and copper ( $1,083^\circ$ ). Not all of these need be determined for a single calibration; three or four points if determined with great accuracy will suffice. Other points may be determined by way of verification, and it is convenient as well to have a large variety of materials to select from so that for any special work the curve may be calibrated by means of substances whose melting or boiling points lie near the temperatures at which

<sup>10</sup> *Journal of the American Chemical Society*, March, 1902

we desire to operate. For instance, one would not ordinarily use the temperatures  $100^{\circ}$ ,  $218^{\circ}$  and  $232^{\circ}$  in constructing a curve for use above  $1,000^{\circ}$ , but would choose  $655^{\circ}$ ,  $1,064^{\circ}$  and  $1,083^{\circ}$ , or other temperatures in this region which are well established as the melting-point of potassium sulphate ( $1,084^{\circ}$ ), or sodium carbonate ( $850^{\circ}$ ).

In using the thermo-couple to obtain a cooling-curve of a metal or alloy it is only necessary to insert the couple, suitably protected by a fire-clay or porcelain tube, into the molten mass. A current of electricity is generated whose electromotive force is approximately proportional to the temperature, or rather the current gives us a measure of the difference in temperature between the hot and cold junctions of the couple. If now this current be passed through a reflecting galvanometer, the beam of light moves rapidly from left to right until it attains a deflection proportional to the temperature measured. This beam of light falls

upon the scale which has been calibrated by the establishment of certain fixed points as just explained. If the beam passes through a narrow horizontal slit in a recording device, behind which a photographic plate is rising or falling at a uniform rate, we obtain a cooling-curve whose co-ordinates are time and temperature. The type of curves given by a pure metal, by surfusion and impure metals has already been shown in Fig. 2. Two other classes of alloys give a cooling-curve identical with that of a pure metal, viz.: eutectic alloys and intermetallic compounds, that is these three classes of substances freeze at a single temperature. The nature of a eutectic will be discussed later; suffice it here to define it as that alloy of a series which has the lowest freezing-point, which is constant in composition, and which is not a chemical compound of the metals which compose it. In Fig. 5, the curve  $AB$  represents that of a homogeneous solid solution. It shows but one "break," though the temperature does not remain constant during the whole period of solidification, as in the case of pure metals, compounds and

eutectics. In  $A' B'$  is shown a curve with two "breaks," the upper one resembling that of a solid solution and the lower one shows the form of a eutectic. The first abrupt change in direction in either of these curves indicates the temperature at which solidification begins. As the excess of one metal solidifies the concentration of the residual fluid is increased with respect to the metal which is not in excess. The ultimate cause of the change in direction is the liberation of the latent heat of solution or of fusion.

As is well known, when concentrated hydrochloric acid (solution of hydrochloric acid gas in water) is boiled, the hydrochloric acid gas evaporates faster than the water. If dilute hydrochloric acid is boiled, the water evaporates relatively faster than the gas. The inevitable result is that at a certain concentration hydrochloric acid and water vapor leave the liquid at a rate proportional to their concentration; thereafter the composition of the liquid remains constant and the boiling point fixed.

A somewhat analogous condition is that of the solidification of two metals,  $M$  and  $N$ . Either of them may be considered as the solvent. If  $M$  is the solvent and  $N$  the dissolved substance, then on cooling such alloy,  $M$  crystallizes first retaining some  $N$  in solid solution. Similarly an alloy containing much  $N$  and little  $M$  begins to solidify by the separation of crystals of nearly pure  $N$  containing  $M$  in solid solution. As  $M$  or  $N$  begin to separate out in solid form the remaining liquid portions become concentrated in respect to  $N$  and  $M$  respectively. The freezing-point of the remaining liquid is thus continually lowered. Eventually either of these classes of alloys reaches a concentration greater than that of a saturated solid solution and then there crystallizes out simultaneously two solid solutions, one of which is a saturated solid solution of  $M$  in  $N$  and the other a saturated solid solution of  $N$  in  $M$ . In any one series of metals this takes place at a definite fixed temperature which is the lowest freezing-point in the series and no matter what the original composition of the alloy, the part solidifying at this constant temperature is uniform in composition. This is the "eutectic" alloy; it will be considered more fully later in this paper.

Some students of alloys consider that at temperatures between the first separation of solid and the point at which the residue solidifies as a whole, there does not exist a homogeneous condition in the still liquid portions. They liken alloys within this range to an emulsion, or conjugate solutions, etc., simply because ultimately the mass solidifies in a banded or laminated mass characteristic of eutectics. It is not necessary, however, to consider that the two solid solutions constituting the ordinary eutectic existed as such in an emulsified state above the eutectic point. To be sure, the microscope reveals a very marked separation of the alloy into two constituents (when there is any eutectic), usually with characteristically laminated structure, but these two components show no tendency to separate into layers when the alloy is kept for a long time just above its eutectic point; on the other hand, the magnitude of the eutectic structure is markedly influenced by the slowness of cooling. Furthermore there is always an evolution of heat during the freezing of a eutectic which is very decided and may well be accounted for by such a marked molecular rearrangement as the formation of a laminated structure from a homogeneous mass would involve, and lastly, we

might cite some concrete evidence on this point which was brought to my attention by Mr. William Campbell. As is well known the constituent of steel known as martensite which is a solid solution of iron carbide in iron is capable of splitting up at about  $690^{\circ}\text{C}$ . or nearly  $800^{\circ}\text{C}$ . below its freezing-point into the beautifully characteristic structure known as pearlite; accompanying this change is a marked evolution of heat, the critical point Ar1 of Osmond. If such a decided transformation can take place in solid steel, it surely ought not to be thought improbable that a similar one could take place in an alloy at the instant of final solidification when the molecular freedom of the particles is doubtless many times as great as in the example cited.

A cooling curve often shows more critical points or "breaks" than simply the upper one indicating the initial freezing-point and the one indicating the freezing-point of the eutectic alloy. Such subsidiary "breaks" are due to molecular changes in the solid substance and must often be considered as truly allotropic.<sup>11</sup> The purest electro-deposited iron shows at least five breaks in its cooling curve below the initial freezing-point. Of course there is no eutectic, and so a cause must be sought for the other five critical points. The lower two seem to be due to occluded hydrogen, while the two occurring at about  $766^{\circ}$  and  $890^{\circ}$  probably indicate allotropic transformations in the pure iron. It is now quite generally agreed that such allotropy exists, and the three varieties are designated as alpha, beta, and gamma iron. Metals and alloys which exhibited such critical points in their cooling curves will probably show corresponding critical points in their thermo-electric or electrical conductivity curves.<sup>12</sup> It has been objected that a slight change in the direction of a cooling curve is not sufficient evidence upon which to base an assumption of allotropy. Perhaps this is a just criticism, but if, having found such a critical point in the cooling curve, we further show that the material under investigation exhibits a sudden change in thermo-electric capacity at exactly that same temperature, and if we find that its electrical conductivity suddenly changes at that identical point we have considerable evidence that above that critical point we are virtually dealing with a new substance. If one is still skeptical as to the meaning of this point, the microscopic examination of the substance quenched from various temperatures above and below the critical point, will usually remove the doubt.

*Molecular Depression of the Freezing-Point of Metals.*—In 1889, Prof. Ramsey<sup>13</sup> determined the molecular weight of many of the metals by the method of measuring the change in vapor pressure when certain known weights of solid metals were dissolved in mercury. He also made determinations at the boiling-point of mercury. From these experiments he states "that it would appear legitimate to infer that in solution, as a rule, the atom of a metal is identical with its molecule."

Messrs. Heycock and Neville found that when two metals were melted together, considering M as solvent and N as the dissolved metal, then

(1) The freezing-point of M is lowered,—the most frequent result.

<sup>11</sup> Stansfield, Fifth Report, Alloys Research Committee of the Institution of Mechanical Engineers, 1899.

<sup>12</sup> Le Chatelier, "Sur la Résistance Electrique des Alliages," in *Contribution a l'Etude des Alliages*, Paris, 1901.

<sup>13</sup> *Transactions of the Chemical Society*, 1889, (55), p. 521.

(2) The freezing-point of M is raised, *e.g.*, silver in cadmium, and antimony in tin.

(3) The freezing-point is unchanged, *e.g.*, thallium in lead, and, I believe, within narrow limits, silver in gold.

But these skillful investigators, to whom we are so much indebted for their careful researches upon alloys, went further and showed that none of these cases contradicted Van't Hoff's theory of solution. This they did in each case by filtering off the part first solidifying. In the first case the more fusible filtrate was found to be richer in the dissolved metal than were the first crystals. In the second instance the crystals were richer in the dissolved metal; that is, the excess of solvent was not first to separate in the solid form but what was probably a definite compound of the two metals having a higher melting point than the metal M, which was assumed to be the solvent. In the third case there was absolutely no separation of the two metals during cooling; that is, the first crystals and the fluid part were identical in composition. That is, the two metals in these instances form isomorphous mixtures. In all their experiments, Messrs. Heycock and Neville were dealing with dilute solutions in which, as in the case of salts dissolved in water, it might be expected that the molecules of the dissolved substance would obey the laws of gases. When their experiments were conducted quantitatively, Heycock and Neville<sup>14</sup> found that two of the empirical laws of Coppey and Raoult hold good for alloys, *viz.*:—

(1) For moderate concentration the fall of freezing-point is proportional to the weight of dissolved substance present in a constant weight of solvent, and

(2) When the falls produced in the same solvent by different metals are compared, it is found that a molecular weight of a dissolved metal produces the same fall whatever the metal is.

In these experiments tin was the solvent, and it was assumed that the metals are monatomic in solution or that their molecules are of one type,— $R_n$  when  $n$  is constant and probably equal to 1.

The third law is probably incorrect, for it assumes that if a constant number of molecules of solvent be employed, the fall is independent of the nature of the solvent. The solvent in the case of metals often tends to chemical combination with the other metal. Thus, gold in 100 atoms of sodium gave 4°C. depression in the freezing-point; in tin, 3°C. and in potassium only 1.8°C.

**Freezing-Point Curves.**—One must not confuse cooling-curves and freezing-point curves. The former, as already pointed out, result during the cooling of a single metal or alloy and time and temperature are the co-ordinates of such curves. When a series of such curves are obtained for any pair of metals mixed in all proportions from 0 to 100% M in 100 to 0% N, and the critical points are plotted in a diagram of which the co-ordinates are temperature and composition we get what is known as a freezing-point curve. That is, the points at which all possible combinations of the two metals freeze are indicated more or less accurately. The more points in the curve actually determined, the more likely becomes the accuracy of the other points. Subsidiary points in the cooling-curves may also be plotted, though they are not strictly speaking freezing-points. Fig. 6

<sup>14</sup> Heycock and Neville, *Transactions of the Chemical Society*, 1880 (57), p. 376

is taken from a paper upon "La Constitution des Alliages Metalliques," by Robert-Austen and Stansfield, which was presented at the Physical Congress, Paris, 1900. The vertical co-ordinate is temperature and the horizontal one represents both time (for cooling-curves) and composition (for the freezing-point curve). It shows graphically how a complete freezing-point curve is constructed from cooling-curves. It will be noticed that the metals *A* and *B* forming the alloy give

cooling-curves of the type of pure metals. In the curves showing a eutectic break, it will be noticed that the magnitude of the eutectic break as compared with the upper or freezing-point break becomes relatively greater as we approach the composition of the alloy *c* which is pure eutectic and gives a cooling-curve identical in form with those of *A* and *B*. In fact this ratio gives a rough approximation of the proportion of the alloy which consists of solid solution separating at the

first break and eutectic alloy crystallizing at the fixed temperature indicated by the horizontal part of the cooling-curve; or, in other words, if the alloy consists mostly of solid solution and a little eutectic, it will take the former longer to solidify than it does the latter and the cooling-curve indicates this roughly.

Freezing-point curves conform in general to three types, as shown in Fig. 7. These curves are not drawn exactly to scale, but are approximately correct. Gold and silver alloys form perfectly isomorphous mixtures, and their freezing-points give almost a straight line joining the freezing-points of the pure metals. Copper and silver give the typical curve of two metals, which mix in all proportions, but do not unite chemically. Antimony and copper unite to give the highly-colored compound known as regulus of Venus,  $\text{Cu}_2\text{Sb}$ .<sup>15</sup> This compound is indicated in the cooling-curve by the intermediate summit. In general such a summit will be found to occur at a formula percentage, and indicates an intermetallic compound. To explain such a curve, we have only to consider it as made up of separate sections, as indicated in the figure by a dotted line. The intermetallic compound has a melting-point of its own, quite independent of that of the constituent metals. It may be higher, lower or intermediate as compared with the constituent metals which compose it. In such a curve as the *Sb-Cu* one, we may consider that one series of alloys is composed of mixtures of Sb and  $\text{SbCu}_2$ , and the other of  $\text{SbCu}_2$  and Cu. We are virtually dealing with two distinct series of alloys, each of which taken separately is of the simple type illustrated by the

*Ag-Cu* curve. In the  $\text{Sb-SbCu}_2$  portion of the curve there is no free copper, and in the  $\text{Cu-SbCu}_2$  portion of the curve there is no free antimony. Dissociation of the compound might make some modification of the above statement necessary, and, indeed, it has been suggested that dissociation causes a summit to appear rounded instead of angular. Curves containing more than one summit may be similarly resolved into series of two components, which may be respectively a metal and an intermetallic compound, or, if between two summits, the components are both intermetallic compounds. An ideal representation of such a curve is shown in Fig. 8. In this figure we see that alloys whose compositions fall between 1 and 2 consist of metal A and compound  $\text{Ax By}$ ; alloys between 2 and 3 consist of components  $\text{Ax By}$ , and  $\text{Ax' By'}$ —they contain no free A or B; alloys between 3 and 4 consist of compound  $\text{Ax' By'}$  and metal B. Each of these pairs of components has its melting-point depressed by the presence in it of the adjacent component. Our *Cu-Al* curve (Fig. 9) may be explained in this way: Two summits occur at the compositions corresponding to  $\text{Cu}_2\text{Al}_3$  and  $\text{AlCu}_3$  (48.49% Cu, and 87.6% Cu respectively). Le Chatelier thinks he has detected with the microscope at least four compounds. Our curve gives no indication of them. Our own micro-

<sup>15</sup> The formula usually given in the past was  $\text{Cu}_3\text{Sb}_2$ , but Stead says the purple constituent is  $\text{Cu}_2\text{Sb}$ .

scopic study of these alloys is not yet completed.<sup>16</sup> Our *Al-Sb* curve (Fig. 9) shows the presence of a compound whose melting-point is more than 400°C. above that of either constituent. Its formula is  $\text{SbAl}$  (81.6% Sb). In this series of alloys we are dealing with two pairs of constituents, *Al-AlSb* and *AlSb-Sb*. The compound seems to be almost insoluble in either of the pure metals, but on theoretical grounds we should expect to find a slight depression in the freezing-point of each metal as indicated in the curve. These points have not as yet been experimentally

detected. The tin-aluminum curve shows a fall of 3° or 4°C. by the addition of 0.5% Al, while with increased additions of aluminum the freezing-point is raised 300°C. at a concentration of 10% Al, 90% Sn.

If in a certain series of alloys we get a freezing-curve with a summit occurring at a formula percentage, and examine the alloys whose freezing-points give rise to that summit, we shall find that in general an intermetallic compound in the

<sup>16</sup> Recent work by Mr. Campbell, soon to be published, shows the *AlCu* series to be quite as complicated as the *CuSn* series, so skillfully worked out by him. (*Proceedings of the Institution of Mechanical Engineers*, 1901.)

pure state presents under the microscope a homogeneous mass made up of crystals, all of which are the same. As we descend from the summit on either branch of the curve we find these crystals becoming less and less in number and size, and at the next angle in the curve they disappear entirely. This is illustrated by the accompanying photographs of antimony-aluminum alloys. These microphotographs were made by Mr. Campbell.

Fig. 10.—20% Sb, 80% Al  $\times 33$  diameters, oblique illumination, shows crystals of SbAl in granular ground mass of nearly pure Al.

Fig. 11.—50% Sb, 50% Al  $\times 33$  diameters, oblique. Crystals of SbAl increasing in size and amount, ground mass decreasing.

Fig. 12.—82% Sb, 18% Al  $\times 16$  diameters, vertical illumination. This photograph shows nearly pure SbAl.

Fig. 13.—85% Sb, 15% Al  $\times 33$  diameters, vertical illumination. We have passed the summit of the curve; the ground mass of aluminum has disappeared and some free antimony is seen.

Fig. 14.—95% Sb, 5% Al  $\times 33$  diameters, oblique. SbAl crystals diminishing in quantity, and ground mass of Sb—probably containing a little SbAl in solid solution—is conspicuous.

Regarding this microscopic evidence, supporting the pyrometric evidence, Mr. Neville<sup>17</sup> says: "These criteria taken together, (1) the occurrence of a summit at a formula percentage, (2) the presence of large crystals of the same kind, decreasing in amount as we descend the branch on either side, are an absolute proof of the reality of a compound."

*The Nature of Eutectics.*—In several portions of this paper eutectic alloys have been mentioned, a term for which we are indebted to Dr. Guthrie, who used it to designate the most fusible alloy of a series—the one which freezes last. There are certain points in which eutectics may differ, and upon these differences they may admit of classification. Every eutectic, however, possesses the following properties:—

1. It is of uniform composition in any one series of alloys.
2. Its freezing-point is constant throughout any one series.
3. The freezing-point is the lowest in the series.
4. It is not a chemical compound.

The composition of a eutectic may and occasionally does correspond to some simple atomic ratio. This coincidence, though striking, does not prove the presence of a compound as the sole constituent of a eutectic. Usually it possesses a laminated micro-structure, and often requires very high magnification to detect the two constituents. Mr. Stead, in his splendid paper upon iron and phosphorus, gives his ideas upon the subject of eutectics, and in addition to what has just been said as to the essentials of a eutectic, he adds some remarks upon what a eutectic may be: (1) "It may consist of two or more metals which do not unite chemically, or (2) of a metal and a definite compound (containing that metal), or (3) possibly of two or more definite compounds. (4) It may consist of a mixture of a solid solution of one metal in another and a free metal. (5) It may contain a solid solution of a definite metallo-metallic salt (intermetallic com-

<sup>17</sup> *British Association Report* (1900), "Upon the Chemical Compounds Contained in Alloys."

pound) and that same metallo-metallic salt in the free state. (6) It may possibly consist of two solid solutions." The last of these statements, which he qualified by the word "possibly," seems to me to be the most important of all; and since I am unwilling to admit that any metal or intermetallic compound ever separates absolutely pure, those conditions in which Mr. Stead speaks of the separation of pure substances seem to me to be inaccurate. The form of the freezing-point curves and the explanation of them according to Prof. Roozeboom renders it highly improbable that any strictly pure material separates at the freezing-point of the eutectic. The most that we can say of the constituents of a eutectic is that in certain cases they are solutions of extreme dilution. In cases where the freezing-point curve lies almost entirely above the melting-point of either or both constituents, but in which there is a slight depression of the freezing-point by very small additions of one metal to the other, as in the case of tin-aluminum, previously mentioned, and when this depression is further indicated in a well-marked eutectic break in other alloys of the series, it may be possible that the eutectic is a single solid solution. The quantity of dissolved metal in such a eutectic might not be enough to change the type of cooling curve seriously, and probably exceedingly high magnification would fail to resolve such an eutectic into two components, for it crystallizes isomorphously with the pure tin, hence it seems that no two juxtaposed constituents are there. This conception of a eutectic is not at variance with the four essentials already enumerated. While not speaking positively on this point, I think it reasonable, and am not sure but that in such a curve as the Sb-Sn curve, where all the points seem to lie above the melting-point of tin, we must consider pure tin as the eutectic—it melts lowest for the series, it is of constant composition, and it is not a chemical compound.

We have now indicated many points of resemblance between metallic mixtures and ordinary solutions. One metal diffuses into another like a salt into water; like two liquids, they may be perfectly miscible or form layers; the layers are not pure, but each contains a little of the other in solution; in general, the solubility increases with the temperatures. They will flow under pressure; they may or they may not react chemically when brought into intimate association by fusion or pressure; the molecular mobility increases with the temperature; upon cooling of binary alloys we observe phenomena strongly suggestive of the freezing of salt solutions; the depression of the freezing-point of one metal when another is added follows the laws of Coppet and Raoult, and the eutectic reminds us very much of the "cryohydrates" of ordinary solutions. Scarcely another point of resemblance is needed, but one is at hand, and a very important one, *viz.*, the phase rule applies quite as well to the explanation of conditions of equilibrium in alloys as it does to the explanation of similar problems in regard to liquid solutions. The classification of the systems, however, requires some modification before the generalizations of Trevor apply, and it is practically somewhat difficult to ensure complete equilibrium in an alloy—the cooling is usually much too rapid to allow of the establishment of equilibrium in the solid mass. If equilibrium has been established, then the number of distinct substances in the mass will depend upon the number of constituents which enter into the composition of the mass. In my

paper already referred to in the *Journal of the Franklin Institute*, February, 1902, I have shown how the adaptation of the phase rule to alloys is accomplished, and as this is more a chemical conception than one of direct interest to engineers, it need not be dwelt upon here. The phase rule does not tell us the number of phases in which one or two components may exist, but how many of them may exist simultaneously in equilibrium. Thus pure iron may exist in three solid, and one liquid phase, but never in all four at one time. Again the iron-carbon alloys, according to Roozeboom, may exhibit at least seven phases, viz., carbon, alpha-, beta- and gamma-iron, liquid solution, solid solution of carbon in gamma-iron, and cementite or iron-carbide. The provisions of the phase rule, however, tell us that only three of these may exist in equilibrium at any given temperature and concentration. Prof. Roozeboom's explanation of a freezing-point curve considered as an equilibrium curve is of great interest in helping to make clear the series of phenomena which are exhibited during the actual solidification of molten alloys. His original explanation was given in connection with the highly complicated iron-carbon curves of Roberts-Austen. It has seemed to me that a simpler figure would lend itself more readily to this explanation and the ac-

companying figure shows the type of curves which gold-copper and copper-silver alloys give, i.e., pairs of metals soluble in each other in all proportions but not forming any compounds. In Fig. 15 the curve  $aec$  represents the temperatures at which for each concentration solidification begins. The curve  $abcd$  shows the temperature at which solidification is complete. Except for the straight portion of this curve,  $bd$ , the exact position of it is a matter of conjecture. According to Stansfield, its position may be calculated with some degree of accuracy upon theoretical grounds, if the latent heat of fusion of the solvent is known and assuming that the dissolved substance is monatomic in the liquid state. The upper line,  $aec$  Roozeboom calls the "liquid" curve, and the lower line,  $abcd$  he calls the "solid" curve. When in a series of alloys the liquid and solid curves have a maximum or minimum point formed by the branches of the curve, they touch at this point as in the curve before us. The point in our diagram where the liquid and solid curves meet is the eutectic point. It means that the liquid represented by the composition corresponding to that point solidifies as a whole at a single temperature. Curves similar to this may be used to explain such complicated freezing-point curves as that of the Al-Cu series, remembering that

the termini of the liquid and solid curves are not necessarily pure metals, but may be a metal and a compound, or perhaps two compounds. The more or less triangular areas,  $a b e$  and  $c d e$  represent mixtures of liquid and solid phases. The areas  $a b r f$  and  $c d g s$  are solid solutions, and in the area  $b d f g$  we have a conglomerate of eutectic alloy, with varying amounts of crystals of solid solution depending upon the composition of the alloy from which they were derived. At the single composition  $e$ , however, we have an exception to this statement, for this alloy consists of eutectic only, while to the left of this the conglomerate consists of eutectic plus solid solutions of N in M, and in alloys represented by compositions to the right of  $e$  we have eutectic (always constant in composition) plus more or less of a solid solution of M in N.

Above the liquid curve we have only liquid phases; below the solid curve we have only solid phases, while intermediate areas correspond to a mixture of liquid and solid phases.

Any alloy whose composition falls within the areas marked solid solution gives but one break in the cooling curve. Alloys represented by compositions falling within the area of the eutectic (except alloy  $e$ ) give two breaks in the cooling-curves. The eutectic itself consists of two solid solutions, whose compositions are indicated by compositions corresponding to the extreme ends of the eutectic line, viz.,  $b$  and  $d$ . However, since the solubility of one metal in another is a function of the temperature below its freezing-point as well as above, we may assume that the solubility in the two components of the eutectic decreases slightly even after solidification, and therefore the lines  $b f$  and  $d g$  are represented as slanting rather than perpendicular to the composition line. These lines indicate the maximum solubility of either metal in the other at temperatures below the freezing-point of the eutectic.

Let us consider the phenomena of solidification of an alloy represented by a composition on  $a e$ , as explained by Roozeboom. Any solution represented by the composition  $m$  begins to solidify at that temperature by the separation of crystals of the composition  $n$ . They therefore contain less of N than the liquid alloy  $m$ . The residual alloy has therefore become enriched in N, and its freezing point is lowered; its composition passes thus from  $m$  to  $p$ , at which point solidification is complete, for at this point the temperature has fallen till it encounters the solid curve at the point  $o$ . The point  $o$ , moreover, indicates the composition of the last crystals to solidify. That is, while the liquid solution is changing from  $m$  to  $p$ , the composition of the crystals has changed from  $n$  to  $o$ . Complete solidification has thus taken place through an interval,  $m o$ . Now there is an alloy whose final solidifying point is  $b$ ; and according to Roozeboom's explanation it is an alloy of composition,  $e$ , which is freezing. At the same temperature, however, occurs the solidification of the solid solution of composition  $d$ . Finally, then, all alloys represented by compositions between 1 and 2, after separating out crystals of solid solutions of N in M, or M in N, represented by compositions along the lines 3, 1 and 2, 4, respectively, become concentrated to the composition  $e$ , where saturated solid solutions of compositions  $b$  and  $d$  solidify side by side, constituting the eutectic. That is, an alloy the vertical projection of whose composition upon the solid curve does not cut the eutectic line, consists of a single solid solution. An alloy whose

composition projected vertically intersects the eutectic line, consists of a conglomerate of eutectic of constant composition  $e$  and a solid solution, whose composition is represented by the horizontal projection of its composition upon the corresponding solid curve. At temperatures and concentrations lying within the areas enclosed by the liquid and solid curves there exists in equilibrium solid and liquid solutions, *e.g.*, at a temperature and concentration represented on the line  $m n$  there exists simultaneously liquid solution  $m$  and solid solution  $n$ .

Great as has been the progress in alloys research within the past few years, yet much remains to be done. When many sets of complete freezing-point curves have been determined, when all the alloys of these series have been examined metallographically, and when their ordinary physical tests, tensile strength, electrical and heat conductivity, specific gravities, etc., have been accurately worked out, then we may be able to generalize and to predict properties of new pairs of metals as well as to set out intelligently to produce new and useful alloys. It must be admitted that the production of alloys in the past has been by the very wasteful method of chance. I hope to see the manufacture of alloys become an exact science and that ultimately even ternary or more complex alloys may be brought within the range of applicability of "natural laws," which as yet remain undiscovered. We are making progress in the right direction, but American scientists have not yet assumed their due share of this task. It is time that we followed the example of the British Association, the Société d'Encouragement pour l'Industrie Nationale, the Institution of Mechanical Engineers and the National Physical Laboratory of Great Britain, in promoting the scientific study of problems in connection with alloys.

# REVIEW OF THE LITERATURE ON ORE DRESSING IN 1901.

BY R. H. RICHARDS.

## CRUSHING MACHINERY.

*Hall's Multiple Action Ore Crusher.*<sup>1</sup>—This breaker is practically a duplex Blake, the moving jaw being divided vertically into two parts so that when one half is working forward, the other is returning, which ensures more uniform and continuous running, and equalizes the strains; furthermore, the required maximum effort is only one-half as great as that of an ordinary Blake breaker of equal capacity, the former crushing all the time and the latter only one-half of the time.

*Huntington Mills.*<sup>2</sup>—At the Butte and Boston mill, Butte, Mont., these mills crush coarse jig-tailings having an average size of 0.25 in. to 20 mesh. The capacity of each mill is 75 tons per day.

*Chilled Steel Roll Shells.*<sup>3</sup>—At a mill in Lauthenthal experiments are in progress with chilled steel and cast steel shells; a partial report is as follows:—

| Shell.            | Working Time.       | Ore Crushed. | Wear. | Price per Pair. |
|-------------------|---------------------|--------------|-------|-----------------|
|                   | 1901.               | Cu.m.        | Mm.   |                 |
| Chilled Steel.... | June 28 to Nov. 20. | 2,639        | 24    | \$92.68         |
| Cast Steel.....   | July 6 to Nov. 20.  | 1,969        | 29    | 57.18           |

In view of the longer life of the chilled steel shells and the consequent decreased running cost, it is probable that they will be substituted for the cast steel shells. A calculation based on a comparison of the wear per ton of ore crushed and the respective costs of the shells show a difference of about half a per cent. in favor of chilled steel.

## CLASSIFIERS.

*The Klein Classifier* operates as follows: As the ore mixed with water comes from the trommels it passes into a receiving chamber from which it flows into a slightly tapered box-shaped compartment, where the classification takes place. This compartment is about 24 in. long at the base, 9 in. wide, and 9 in. deep.

<sup>1</sup> *Feldens's Magazine*, 1900, Vol. III., p. 539. <sup>2</sup> *Ibid.*, 1901, Vol. IV., p. 243.

<sup>3</sup> *Zeitschrift fuer das Berg-, Huetten-, und Salinenwesen*, 1901, Vol. XLIX., p. 322.

composition projected vertically intersects the eutectic glomerate of eutectic of constant composition  $e$  and a position is represented by the horizontal projection of corresponding solid curve. At temperatures and concentrations enclosed by the liquid and solid curves there exists liquid solutions, *e.g.*, at a temperature and concentration  $m$  there exists simultaneously liquid solution  $m$  and

Great as has been the progress in alloys research yet much remains to be done. When many sets have been determined, when all the alloys of metallographically, and when their ordinary electrical and heat conductivity, specific worked out, then we may be able to generate pairs of metals as well as to set out alloys. It must be admitted that this by the very wasteful method of character become an exact science and that it may be brought within the range yet remain undiscovered. We American scientists have not that we followed the example of the National Physical Laboratory study of problems in

are mounted side ends of rocking arms, mounted through a crank, connecting rod concentrates above the sieve is aided by a puff forward stroke of the plunger. This is under from advantages claimed are: (1) less power required, as may be operated by one eccentric; (2) greater capacity;

#### FINE CONCENTRATORS.

*Phinwick Concentrator*<sup>7</sup> consists of a stationary rectangular plane table covered with canvas and thickly studded with nails, which act as riffles; the slope of the table depends upon the coarseness of the material to be treated and the action is intermittent. The *New Standard Concentrators*<sup>8</sup> are used at the Last Chance mill, three of these concentrators treating from 15 to 20 tons of ore per table per day, the ratio of concentration being 100 to 1. The tables are of the bump type suspended from three points, and are easily adjusted to wide variations in slope. The strike is usually 0.75 in. and about 225 per minute. The floor space is 11×15 ft. The table is covered with linoleum, and has a water consumption of 3.5 gal. per minute.

<sup>7</sup> Transactions of the American Institute of Mining Engineers, 1901, Vol. XXX.

<sup>8</sup> Mines and Minerals, 1901, Vol. XXII., p. 98.

<sup>9</sup> Transactions of the American Institute of Mining Engineers, 1901, Vol. XXX.

<sup>10</sup> Mines and Minerals, 1901, Vol. XXII., p. 98.

<sup>11</sup> Ibid., p. 99.

Air at about 25 lb. pressure is admitted through six holes 0·375-in. diameter in the base and on the sides through hoods with sprays of perforated copper. Hydraulic water is introduced by two 1·25-in. pipes. The outlet pipe is on a line with the hydraulic pipe, and is 2 in. above the base of the box. The air as it comes from the bottom of the classifier carries to the top a certain amount of fine material while the larger particles remain behind and are washed out.<sup>4</sup>

*Dimmick Classifiers* are in use at the Helen Mining Co., near Cooney, New Mexico.<sup>5</sup> This apparatus consists of a V-tank 15 ft. long by 10 ft. high. It has a main central partition with intermediate small partitions. The action is simply that of a distributor, the pulp going to vanners and slime tables.

#### JIGS.

*The New Century Drop Motion Jig*.—This jig does not use eccentrics; it lifts the plunger rod by a cam having a maximum lift of from 1 to 1·5 in., thereby compressing a spring which on the release imparts a quick down thrust. It is adjustable, and hence when working with usual stroke of 0·125 to 0·375 in., it affords the plunger a period of absolute rest; it is also claimed to use less power than with an eccentric jig. This jig is fully described and illustrated by Frank Nicholson in his article on "Mining and Milling in the Joplin District, Missouri," elsewhere in this volume.

*The Klein Jig*<sup>6</sup> is being used in southeast Missouri and in the Philipsburg district of Montana. It very closely resembles the Hartz jig in general form, but instead of driving each plunger by an eccentric, two jigs are mounted side by side and their plungers are driven from opposite ends of rocking arms, mounted on a longitudinal rocker-shaft which is rocked through a crank, connecting rod and eccentric. The discharge of concentrates above the sieve is aided by a puff of compressed air at every downward stroke of the plunger. This is under from 25 to 30 lb. pressure. The advantages claimed are: (1) less power required, as any number of plungers may be operated by one eccentric; (2) greater capacity; (3) cleaner separation.

#### FINE CONCENTRATORS.

*The Dimmick Concentrator*<sup>7</sup> consists of a stationary rectangular plane table covered with canvas and thickly studded with nails, which act as riffles; the slope of the table depends upon the coarseness of the material to be treated and the action is intermittent.

*The New Standard Concentrators*<sup>8</sup> are used at the Last Chance mill, three of these concentrators treating from 15 to 20 tons of ore per table per day, the ratio of concentration being 100 to 1. The tables are of the bump type suspended from three points, and are easily adjusted to wide variations in slope. The strike is usually 0·75 in. and about 225 per minute. The floor space is 11×15 ft. The table is covered with linoleum, and has a water consumption of 3·5 gal. per minute.

<sup>5</sup> *Mines and Minerals*, 1901, Vol. XXII., p. 98.

<sup>6</sup> *Transactions of the American Institute of Mining Engineers*, 1901, Vol. XXX.

<sup>7</sup> *Mines and Minerals*, 1901, Vol. XXII., p. 98.

<sup>8</sup> *Ibid.*, p. 99.

*The Overstrom Table* which appeared in 1901 is the latest form of riffle table. Its shape is that of a rhomboid. The line of the riffle blocks and the direction of motion of the table are the same and are nearly parallel to the shorter diagonal of the rhomboid. This table closely resembles the Wilfley, the principal difference being in a diminution of the idle spaces and in addition to the working spaces.

*The Wilfley Table.*—In a suit brought by A. R. Wilfley against the Denver Engineering Works, a decision was rendered in complainant's favor, the court stating: "It may be that the Cammett tables are an improvement upon the invention covered by the Wilfley patent in this respect (directing and delivering concentrates), but it still has all the essential elements of the best form of Wilfley's invention; it performs the same function in substantially the same way, and therefore must be held to infringe it."

#### ACCESSORY APPARATUS.

*The Scobey Sampler* is a device for sampling material which is transported by water. As shown in Fig. 1, it consists of a belt-driven mechanism which passes

- |                |                     |                   |                   |

FIG. 1.—THE SCOBIE SAMPLER.

a bucket through a falling stream of pulp and water, deflecting only a very small portion to a convenient receptacle. When not taking samples the bucket is automatically locked; it can be adjusted to take from 0.01 to 0.0001 part of whole. The list price of this sampler is \$36 and during the past year it has been endorsed by several prominent milling engineers.

This sampler conforms to the essential rule of taking the whole of the stream part of the time.

*The Geissler Sampler.*—There is nothing new to be added to the description of this sampler already given by Prof. H. O. Hofman in *THE MINERAL INDUSTRY*, 1900, Vol. IX., p. 440.

*An Automatic Sampler*<sup>9</sup> at the Smuggler mills, Aspen, Colo. (which is illustrated in the reference given), consists of a scoop for taking or deflecting a portion of the whole stream of tailings and is suspended from a tippie tank. Water is supplied through a pipe to the high side of the tippie which on filling falls, causing the scoop to pass through the stream. On reaching the lowest portion of its movement a valve is opened by impact allowing the water to discharge into the waste tank. A retarding device is attached to the tippie to prevent too easy movement, making it necessary for the tippie tank to be nearly filled before the movement commences. A pneumatic check is applied to regulate the speed and the quantity taken. The deflected sample is further reduced by a split-shovel arrangement in the sample launder.

A 12-in. *Robins Belt Conveyor*<sup>10</sup> is used at the British Columbia Copper Co.'s plant at Greenwood, B. C., to take the undersize from the grizzly to the ore bins, the oversize passing to a breaker. A 36-in. sorting conveyor, 111 ft. center to center, takes the ore from the breaker to the ore bins. The discards from picking are removed by a 12-in. and a 16-in. conveyor (540 ft. center to center). Picking is reported to cost 6c. per ton.

The Homestake Mining Co. has installed three belt conveyors,<sup>11</sup> each 167 ft. long, to convey ore from the shaft house to the mill. These are driven from the discharge end, require 3 H.P. each and handle 480 tons per 24 hours. The ore is fed by one boy and is sorted in transit, which by removing chips and pieces of wood increases the capacity 10 to 20 tons per day, as the stamp screens do not clog.

*The Jeffrey Belt Conveyor*<sup>12</sup> for handling wet or dry ore is now arranged so that the belt may be made concave or convex, which allows the water to drain off in the latter case.

#### TESTING DEVICES.

*A New Laboratory Classifier*<sup>13</sup> has been constructed by Prof. Henry S. Munroe (see Fig. 2). In the original classifier the material was fed through a stop-cock funnel, a method which seriously limited the capacity and efficiency of the apparatus. The funnel is now replaced by a second Erlenmeyer flask connected directly with the apparatus by a short length of rubber tubing of large diameter.

*Laboratory Slime Table.*<sup>14</sup>—Prof. Henry S. Munroe has also constructed an excellent rectangular slime table for laboratory use consisting of a strong metal frame about 5 ft. long in which flat plates may be secured. The means of varying the adjustments have been carefully designed and some of the usual difficulties overcome. The table is illustrated in Fig. 3.

<sup>9</sup> S. I. Hallett, *Mining and Scientific Press*, 1901, Vol. LXXXIII., p. 55.

FIG. 3.—A LABORATORY SLIME TABLE.

the mill results which allows the company to buy small lots of ore and to mill them collectively instead of separately as before.

#### MILLS AND GENERAL MILLING CONSIDERATIONS.

*The Helena-Frisco Concentrator*,<sup>16</sup> at Gem, Idaho, treats daily about 600 tons of argentiferous galena carrying a considerable amount of blende. The following outline is given of the process of working: The ore from the mine is trammed to the mill bin (1).

- (1) Mill Bin to (2).
- (2) Grizzly. Oversize to (3); undersize to (4).
- (3) One 10×20-in. Blake breaker set at 1 to 1.25 in., to (4).
- (4) One pair No. 1 Rolls, 30×15 in. set at 0.75 in. to (5).
- (5) Two No. 1 trommels, with 10 mm. and 15 mm. holes. Over 15 mm. to (6); through 15 on 10 mm. to (7); through 10 mm. to (10).
- (6) Three 3-compartment Bull Jigs. Heads to (8); tailings to waste.
- (7) Six 4-compartment Hartz Jigs (four of which treat material 15 mm. on 10, and two 7 mm. on 10). First and second discharges to (34); third and fourth discharge to (8); tailings to (36).
- (8) No. 1 Elevator to (9).

<sup>15</sup> *Mining and Scientific Press*, 1901, Vol. LXXXIII., p. 130.

<sup>16</sup> *Journal of Canadian Mining Institute*, 1901, Vol. IV., p. 254.

- (9) One pair No. 2 Rolls, 36×14 in. to (5).
- (10) Two No. 2 trommels, with 3, 5, and 7 mm. holes; over 7 mm. to (?); through 7 on 5 mm. to (11); through 5 on 3 mm. to (12); through 3 mm. to (12).
- (11) Two 4-compartment Hartz Jigs; first and second discharges to (34); third and fourth to (14); tailings to (36).
- (12) One Calumet Classifier. First, 2d, 3d, 4th, and 5th spigots to (13); overflow to (24).
- (13) Eight 4-compartment Hartz Jigs. First and 2d discharges to (34); 3d and 4th discharges to (14); tailings to (36).
- (14) Settling box. Spigot to (16); overflow to (15).
- (15) Long settling tank. Spigots to (16); overflow to (35).
- (16) No. 2 Elevator. To (17).
- (17) Two pairs No. 3 Rolls, 30×14 in. to (18).
- (18) One trommel with 3-mm. holes. Oversize to (19); undersize to (21).
- (19) No. 3 Elevator. To (20).
- (20) One pair No. 4 Rolls 24×14 in. To (18).
- (21) Two Calumet Classifiers. First and 2d spigots to (22); 3d, 4th and 5th spigots to (23); overflow to (24).
- (22) Four 4-compartment Hartz Jigs. First, 2d, and 3d discharges to (34); 4th discharges to (14); no tailings made; overflow to (36).
- (23) Four 4-compartment Hartz Jigs. First and 2d discharges to (34); 3d and 4th discharges to (14); no tailings made; overflow to (36).
- (24) Settling tank. Spigot to (25); overflow to (28).
- (25) Nine convex revolving slime tables. Heads to (34); middlings to (36); tailings to (36).
- (26) No. 4 Elevator to (27).
- (27) Settling tank. Spigot to (29); overflow to (30).
- (28) Settling tank. Spigot to (29); overflow to (30).
- (29) Ten 6-ft. Frue vanners. Heads to (34); tailings to (31).
- (30) Outside settling tank. Spigot to (31); overflow to (36).
- (31) Settling tank. Spigot to (32); overflow to (36).
- (32) Four 6-ft. and four 4-ft. Frue vanners. Heads to (33); tailings to (36).
- (33) Ore pile (finished product).
- (34) Two concentrates settling boxes. Overflow to (35).
- (35) Overflow settling box; settlings returned to mill; overflow to (36).
- (36) Tail race to waste.

*In the Galena-Joplin Lead and Zinc district*<sup>17</sup> similar methods of milling are generally employed with the exception that classifiers are used extensively in the Joplin section, and rarely in the Galena section. The following is the general method of milling. The ore from the mine goes to (1).

- (1) Grizzlies. Oversize to (2); undersize to (3).
- (2) Sledge. To (3).
- (3) Breaker. To (4).
- (4) No. 1 Rolls. To (5).

<sup>17</sup> *Mines and Minerals*, 1901, Vol. XXI., p. 465.

- (5) No. 1 elevator. To (6).
- (6) Trommel. Oversize to (8); undersize to (7).
- (7) No. 1 or roughing jig. Heads to (9); middlings to (10); tailings to waste.
- (8) No. 2 Rolls to (5) and (6).
- (9) No. 2 elevator. To (11).
- (10) No. 3 elevator. To (12).
- (11) No. 2 or cleaning jig. Heads to market; middlings to (13); tailings to waste.
- (12) No. 3 rolls. To (5).
- (13) No. 4 elevator. To (14).
- (14) Sand jig. Heads to market; middlings to (15); tailings to waste.
- (15) Slime treatment (sludge mills).

When classifiers are used they are generally attached to the rear end of the No. 2 or cleaning jig and are also arranged to receive the drain from the hutch work of the jigs. The slimes are treated at centrally located sludge mills for the production of fine concentrates.

*The sludge mills* work on slimes and tailings, averaging between 3% and 7% blende. The concentration is accomplished by rolls, jigs and buddles; or by Wilfley tables. The capacity in both cases is small because of the lean tailings and slimes, due to the increasing care exercised by the large mills. In the first type of sludge mill the material receives no further crushing after leaving the jigs. The heads from the cleaner and sand jigs are the only products which are directly marketable to the smelter. The middlings and slimes from the jigs go to roughing and cleaning buddles for final treatment. In the second type of mill Wilfley tables are used as roughers and cleaners, usually one cleaner to two roughers. As the sludge mills are independent of the large mills it would seem that a great saving could be made at the latter by introducing some form of slime treatment for the rich slimes from the cleaner or sand jigs before they become mixed with waste material and become worthless. A step has been taken in the right direction by the operators in the Joplin portion of the district where classifiers are employed to save jig slimes. The attempts made to use the round table have been unsuccessful.

*At the Ashio Mill, Japan*,<sup>18</sup> a separate concentration is used for each of the two classes of ore, with the exception of four products from the first class, which are run into the second. The ore consists of copper pyrites associated with iron pyrites, galena, arsenopyrite and blende; the first class ore averages from 11% to 12% Cu, and the second class about 1.5% Cu; the former is concentrated to 20% Cu, while the latter is brought up to 12% Cu; the mixed concentrates are sent to the smelter, and average 16% Cu. The arrangements of the mills are similar, consisting of rock breakers, trommels, cobbing tables, rolls, jigs and settling tanks. It is stated that from 87% to 92% of the copper content of the first class ore is saved, and from 59% to 65% ore of the second class.

*The Humphreys Mill*,<sup>19</sup> at Creede, Colorado, upon its completion will dress ores

<sup>18</sup> *Berg- und Huettenmaennische Zeitung*, 1901, Vol. LX., p. 261.

<sup>19</sup> *Mining and Scientific Press*, 1901, Vol. LXXXIII., p. 218.

as follows: from bins to grizzly by trams; oversize going to 10×30-in. breaker, joins the undersize and goes through an automatic sampler to a roughing trommel; thence to two sets of 14×36-in. rolls; then elevated and passed through two sets of screen lines each consisting of four 3×6-ft. screens. Everything above 16-mesh is handled by 4-compartment Hartz jigs, while through 16-mesh is run to four Bartlett tables. Tailings are reground in three sets of 14×30-in. rolls, sized by revolving screens, the oversize being elevated by Frenier sand pumps; the pulp is classified in hydraulic sizers and distributed on 12 Wilfley tables. The capacity of the mill is expected to be 150 tons per day.

*The Chainman Mill, at Ely, Nevada,*<sup>20</sup> is in process of construction, and will consist of eight departments, *i.e.*, screening and crushing, amalgamating, concentrating, sizing and settling, leaching, precipitating, slimes treatment, refining and assaying. The crushing will be done by an Austin gyratory breaker followed by rolls, from which ore goes to Chile mills, thence over plates to Cammett tables, and then to settling tanks for leaching treatment.

*Canvas Table Plant.*—At the Mitchell and Mussigbrod mill at Garnet, Montana,<sup>21</sup> a canvas table plant has been used with success. The ore milled is a sulphide carrying gold which is crushed to 30-mesh by stamps; the pulp passes over silver-plated copper plates, thence to three vanners, thence to two Wilfleys, and thence to a canvas table, which is the old German *Kehrherd* consisting of an inclined floor 34 ft. long by 38 ft. wide, with a slope of 1 in 10. The runs are 2 ft. wide, and while one is being swept, two others are shut off and are being cleaned by wash water; the sweeping of 400 sq. ft. of table occupies 30 minutes and requires 260 cu. ft. of clean water. The slimes go to a series of settling tanks and boxes.

The mill treats about 30 tons per day of ore, consisting of quartz with mixed sulphides. The vanner concentrates contain 30%  $\text{SiO}_2$ , the Wilfley concentrates contain 50%  $\text{SiO}_2$ , and the slimes about 70%  $\text{SiO}_2$ . During April, 1901, the three vanners made 43 tons of concentrates of 7 oz. gold per ton; the two Wilfleys produced 7.5 tons of concentrates of 7 oz. gold per ton, and the canvas table 8.5 tons of slimes of 7.33 oz. per ton.

*At the Portland direct wet-crushing cyanide mill, Black Hills,*<sup>22</sup> the battery pulp runs to a spiral sand pump which elevates it to the slime sand separators. The box now in use, shown in Fig. 4, is about 3×4×5 ft. The inlet *I* is a 3.5-in. pipe from the spiral pump; the outlet *O* is a square covered launder, 12 in. wide and 5 in. high; *D* is the bottom discharge door. When the box fills with sand to *O* it is dumped through *D*. The separation which is given in the table on the following page, has been effected on pulp from twenty 900-lb. stamps, dropping 8 in. 94 times per minute, crushing a siliceous refractory ore through 10-mesh and 20-mesh standard wire screens.

*Grund in the Hartz Mountains,*<sup>23</sup>—The following changes have been made at the establishments in this locality: the use of 3- and 4-sieve jigs instead of the 2-sieve; the use of rolls instead of stamps. By these changes it is possible at

expensive slime separation. The former jig tailings ran from 2 to 8 mm., while the present product runs up to 32 mm. For dressing ores containing heavy spar, the latter is completely pulverized in stamping, whereas with rolls it is crushed, and the resulting rhombohedrons form small particles which can be drawn off from the jigs.

*The saving of slimes*<sup>24</sup> in the Cœur d'Alène district has been successfully accomplished on a small scale by operators working independently of the mills. The most successful method so far is to run the tailings into V-shaped settling troughs about 30 ft. long, 2 ft. wide at the top and 2 ft. deep, the overflow operating an overshot water wheel which runs a vanner. This has resulted in activity in procuring water rights, and the large mills are adding to their plants in an endeavor to save more of their ore values. Attention is also called to the fact that the largest loss of values is in the jig tailings and although the matter has been the subject of much thought and consideration, the problem of saving these values is yet to be solved.

*The Concentration of Broken Hill (N. S. W.) sulphide ores* was described in detail by Mr. T. J. Greenway in THE MINERAL INDUSTRY, 1900, Vol. IX., p. 745.

*Gypsum Milling methods* are remarkably uniform in Kansas.<sup>25</sup> The gypsum rock and earth from the mine is crushed in breakers and then reduced to flour by flour mills or disintegrators; it is then treated in the calcining kettle, from which it is conducted to bins, thence to bolting cloths and sized, and finally to the shipping department.

*Krupp Ball Mill versus Stamps.*<sup>26</sup>—A five-stamp battery with a stamp weight of 525 kg. (about 1,165 lb.), falling 160 mm. (about 6.5 in.) with 92 drops per minute crushes approximately 780 kg. (about 1,720 lb.) of hard quartz per hour through a No. 40 screen, requiring 12.5 H.P. A No. 3 Krupp Ball mill crushing wet, with 450 kg. of special steel balls, will pass 1,200 kg. (about 2,650 lb.) of the same quartz through the same screen per hour, using only 9 H.P. A mill for dry crushing, as above described, grinds 800 kg. (about 1,770 lb.) per hour under the same conditions, requires 8 H.P., and if necessary, 2 H.P. extra for the exhaust which separates the dust from the sands.

(a) Probably meshes per linear inch.

*Gröndal Ball Mills*<sup>27</sup> are used at Pitkäranta, Finland, to pulverize the iron ore as it comes from the Blake breakers. For hard, but brittle material large balls are used, while for tough ore a larger number of smaller balls. The total weight of the balls varies from 1,000 to 2,000 kg.; the diameter of the balls is not over 150 mm. Running at 25 revolutions per minute and using 80 l. of water per minute the following sizes were obtained: grains over 1.0 mm. = 1.7%; between 1 and 0.5 mm. = 1.2%; between 0.5 and 0.33 mm. = 3.8%; between 0.33 and 0.25 mm. = 7.5%; between 0.25 and 0.16 mm. = 22.4%; between 0.16 and 0.125 mm. = 19.6%; under 0.125 mm. = 43.8%. Using balls of a total weight of 1,500 kg. revolving 28 times per minute, 18 to 20 H.P. is required, which will crush every 24 hours 30 tons of egg sized ore from the breakers through a 1-mm. screen.

*A Coarse Concentrating without Sizing Test*<sup>28</sup> was made on a Georgia ore carrying gold and silver, and iron, lead, zinc, and copper sulphides, finely disseminated in hard quartzite. The ore was crushed to 8-mesh with a jaw breaker and two sets of rolls, and then treated on a Bartlett table without any sizing. The following results were obtained:—

|                            | Ore.      | Concentrates. | Middlings. | Tails.    | Percentage Saved in Concentration.<br>Concentration<br>21.8% of ore. |

The results of crushing and sizing tests made on various ores with different classes of crushers have been carefully tabulated, and are embodied in 16 tables given by G. Bonsall Porter.<sup>29</sup> In the two following tables the crushers used were a 9×12-in. Dodge breaker, a 3.5-ft. Huntington mill, a pair of 16×10-in. rolls, a Gates standard sample grinder, and a 5-stamp battery.

*A Bolivian tin dressing mill*<sup>30</sup> was recently equipped with rock-breakers, rolls, Huntington mills and Frue vanners. The general practice consists of crushing with stamps, sizing by trommel, washing in stationary buddles (rectangular pits), then on round buddles and finally on slime tables; jigs also are used.

(a) 50-mesh sieve used.

## MAGNETIC CONCENTRATION.

At *Pitkäranta, Finland*,<sup>31</sup> with ore containing approximately 30% Fe, and 4 to 5% S, 80 per cent. of the iron content is made up of magnetite, the particles being scarcely larger than 1 mm. The sulphur compounds are blende, pyrrhotite, pyrite and chalcopyrite. The gangue is hard serpentine and malacolite, and contains from 8 to 9% Fe. The plant consists of four Blake breakers, eight Gröndal ball mills, and eight Gröndal magnetic separators. The capacity depends upon the contents of the feed; with the ore described above the capacity is about 30 tons per day; if a greater quantity is fed the separation is unsatisfactory. The separators require a current of six amperes with 31 volts. An average product with 61% Fe contains 0.6% S; with 66% Fe contains 0.24% S and with 68% Fe contains 0.18% S. The finished product is briquetted and heated to 1,200°C. Without this heating the briquettes could only be handled cautiously for fear of breaking.

*Magnetic Separation by the Mechernich Separator.*<sup>32</sup>—The following results were obtained in experimenting with a blende ore carrying barite: with blende fines using 18 volts and 20 amperes, the zinc contents were raised from 40.29% to 49.04%, while the barite contents were reduced from 12.52% to 1.95%; 95.2% of the zinc contents were recovered. With blende fines middlings, the zinc content was raised from 31.73% to 39.66%; this result would have been better had the material been dryer. With blende sands middlings, screened into two products, 0.5 to 1 mm., and 1 to 1.5 mm., using 21 volts and 41 amperes, the zinc content was raised from 41% to 51%; the barite content lowered from 5.6% to 0.5% and 78% of the zinc was saved.

*The Waring System of Magnetic Concentration*<sup>33</sup> is in use at Webb City, Mo., for cleaning zinkiferous concentrates of copper and iron pyrites. The concentrates are dried, put through a 0.25-in. sieve, passed to a mechanical calciner which is adapted to desulphurize partially the pyritic material and to change ferric oxides and ferrous carbonates, chalcopyrite, etc., to the magnetic condition, without in the least degree affecting the blende or such other minerals as are to be separated by magnetic repulsion. The hot material is mechanically cooled and delivered to a Waring separator of the drum type, falling into the intense magnetic field of the peculiarly arranged annular grooves of the machine, from which the diamagnetic blende is expelled by magnetic repulsion aided by centrifugal force; while every particle of magnetic material, no matter how low its magnetic permeability, remains attached to the polar rings, and is released upon arriving at the opposite side of the axis. The first product is quite free from magnetic particles and requires no further treatment. The paramagnetic product passes to a magnetic classifier, which removes the different minerals according to their magnetic permeability. Ordinary pyritiferous zinc ores from Galena, Kan., averaging 44% Zn, 15% Fe (valued at less than \$10 per ton in the ore market), gave a product containing 64% clean blende assaying 64.2% Zn, the burnt pyrites contain 2.8% Zn; the value of the blende product (0.64 ton) from one ton of ore was \$17.92.

A test on a lot of mixed Colorado sulphide ore concentrates (41 tons) worth \$3.30 a ton at the mine, gave 19.5 tons of zinc concentrates worth \$17 per ton, and 21 tons of copper-iron concentrates worth \$18.45 per ton. The cost of magnetic concentration was \$1.10 per ton. The following table gives the values contained in the original material and the resulting products.

*The Wetherill Separator*,<sup>34</sup> treating an ore consisting of galena, blende, spathic iron ore (containing 12% Mn), with a quartz gangue has yielded a blende product with from 42 to 46% Zn, while the spathic iron contains only from 1 to 3% Zn. The tension is 65 volts, and the magnets work with a current of from 5 to 8 volts and from 12 to 16 amperes. With eight men, from 3 to 3.5 tons of ore are treated hourly at a cost of 1s. 5d. (\$0.34) per ton.

*Magnetic Concentration*<sup>35</sup> has been tried on the Broken Hill, N. S. W., sulphide ores, but commercial conditions prevent its use.

*Roasting Zinc Ores.*—In the removal of iron from zinc blende, Dr. Wm. B. Philips<sup>36</sup> finds the roasting temperature to be a very important factor; if over-roasted much iron is thrown over into the zinc heads; it is not necessary to

<sup>36</sup> *Engineering and Mining Journal*, Nov. 30, 1901, p. 710.

remove more than one-third of the sulphur in roasting to obtain the best results.

*Strength of Electric Current.*—E. Langguth<sup>37</sup> considers that the currents used in the electro magnetic separation of ore must have as low an intensity and as great a density as possible, that is to say, intense magnetic fields. The ore must be passed before the separating poles steadily and at as short a distance as possible; and the rate of speed at which this is done must depend on the magnetizability of the ore particles. Finally, the separation must be effected in homogeneous magnetic fields.

At Naeverhaugen, Norway,<sup>38</sup> a red hematite ore containing from 40 to 60% Fe is being concentrated.

*Concentration by static electricity*<sup>39</sup> is the object of a recent patent; the device consists of an endless, electrified traveling belt, fitted with screen capable of electrical repulsive action. Above the belt are two suction hoods to draw off the electrified particles.

*The Wetherill Magnetic Process of Ore Concentration* is described in detail by H. A. J. Wilkens, elsewhere in this volume.

#### PNEUMATIC CONCENTRATION.

*Crown Dry Concentrating System.*<sup>40</sup>—After crushing the ore with rock breaker and rolls arranged to give minimum fines, and sizing through a set of sieves ranging from 40- to 180-mesh, the different sizes of pulp are sent to the concentrator proper, which consists of a woven, corrugated, inclined belt traveling through a closed box with an air chamber under the superior portion. At the head or elevated end of the belt a blower is placed which discharges air horizontally into this chamber. The whole is mounted on a shaking table having a rapid vibratory motion to keep the pulp in active vibration. The air pressure in the box under the belt can only relieve itself through the interstices of the woven belt, and as this is running at an angle of 15° or less, the horizontal air column strikes it at an acute angle and passing through the belt displaces the lighter and worthless grains and causes them to move toward the lower or waste discharge, while the heavier and valuable portion being unaffected is carried on to the upper or concentrate discharge. A recovery of from 85% to 95% of the total sulphides is claimed. A 100-ton plant is in process of erection at the May-day mine, Tintic district, Utah.

#### OIL CONCENTRATION.

*The Elmore Process.*<sup>41</sup>—In treating 5,000 tons of Glasdir ore, assaying 1.5% Cu, 20 to 30 g. silver, and 2.5 g. gold per ton, an extraction of 80% of the values was obtained; the concentrates averaged 10% Cu, 250 g. silver and 25 g. gold. The cost of treatment, including crushing, was \$1.44 per ton; the

<sup>41</sup> *Oesterreichische Zeitschrift*, 1901, Vol. XLIX., p. 307.

oil consumption was from 2 to 2.5 gal. per ton of ore, and the sp. gr. of the oil was 0.9.

An oil plant has been ordered for the Independence mine, Colo., and an option has been taken by Mr. Chas. Butters, representing the Elmore Co., on the tailings dump of the Mammoth Mining Co.,<sup>42</sup> Tintic, Utah, who will give the process a thorough trial. The accompanying table will show what this process has done in the laboratory on different kinds of ores.

RESULTS OF LABORATORY TESTS MADE BY THE ELMORE ORE CONCENTRATING PROCESS ON VARIOUS ORES, SLIMES, TAILINGS, ETC.

(a) Trace. (b) Nearly.

The advantages claimed for this process are as follows: (1) saves the finest slimes; (2) can be used after wet crushing without classification; (3) requires little labor and power; (4) relatively low cost of installation, and small floor space; (5) low operating cost; (6) small water consumption; (7) clean concentrates; the presence of oil is no disadvantage; (8) gives separations impossible with water, such as copper pyrites from magnetite; (9) mechanical appliances

<sup>42</sup> *Engineering and Mining Journal*, June 29, 1901, p. 896.

permit a clean plant, and oil loss is from 1 to 3 gal. per ton of ore; (10) the plant can be enlarged easily; and (11) can work on a great variety of ores.<sup>43</sup>

### COAL WASHING.

*At the Donk Bros. Washing Plant,*<sup>44</sup> designed to wash 60 tons per hour, the raw coal is divided into four sized products by a triple-jacketed screen. The three nut coal sizes go to special jigs which deliver clean nut to the draining elevators and screens. The fine coal goes to a hydraulic grading sizer. This is a V-shaped box having compartments corresponding to the fine coal jigs. Each different product from the box goes to a special fine jig having a special crushed feldspar bed. The clean coal is sluiced from the fine jigs to the drying screen having 0.125-in. openings. The refuse from the nut coal jigs and the waters draining from the nut coal drying screens and the same for the fine coal go to separate sludge elevators which elevate the refuse while the fine coal dust drains out with the water (through the perforations in the buckets), and the fine coal dust is afterward settled out and saved. The clarified water is pumped over again through the circuit.

Attention is called to the following special features of this plant: (1) the extreme and careful grading into different sizes, and washing each size in a jig especially made and adjusted for it; (2) the arrangement of the whole plant with a view to minimizing labor, three men only being required to run it; (3) the effective arrangement for settling the water, and the automatic and continuous removal therefrom of sludge and refuse, clarifying the water, and saving all the fine coal dust; (4) the effective arrangement for drying the washed coal.

*New Coal-Screening and Washing Plant at a Belgian Colliery.*<sup>45</sup>—Coal up to 2.5-in. size is screened, the total output passing to coking ovens. There are five products from the four-part conical screen; the finest product or dust, is passed without washing via elevators, etc., directly to the storage bins; the four larger sizes are sluiced down chutes to the washing plant arranged on the Francou system. The largest three of these sizes are treated each in a separate washing tank (jig). The fourth or smallest size (next to the dust) is treated in two washing tanks. The stones (waste) from all five of these washing tanks are washed over again in a sixth tank and are then sent to a storage bin. The fine slates traversing the filtering bed and the washing table do not contain any coal whatever, but are discharged to settling tanks. The washed coal is drained on sloping tables and in perforated sloping troughs up which they are elevated and finally crushed in a Deville crusher and elevated to the storage bins. The washed coal must not contain more than 8% moisture on leaving the washing plant, in order that it may be crushed and delivered to the storage towers dry enough for coking.

*The Screening of Anthracite.*<sup>46</sup>—At the breaker of the Delaware, Lackawanna and Western Railroad, the entire product, barring the fines, can be turned out

## ED CARBONIC ACID GAS.

BY AUGUSTE J. ROSSI.

—Carbon dioxide, carbonic anhydride, or as it is commonly but called, "carbonic acid gas," is widely distributed in nature. In the condition, it forms an essential element of the atmosphere to the extent of four volumes in 10,000; and it is given off spontaneously from the fissures of rocks in certain grottoes; it is also found at the bottom of the shafts of a few lead mines in France. Under the influence of light, plants decompose the carbon dioxide of the atmosphere, retaining the carbon to aid in building up the plant structure and setting free the oxygen; carbon dioxide is also found in soils, from which it is extracted by rain and other surface waters. It is the ultimate product of the fermentation of many liquids as well as of the destruction of organic matter and it is a product of the combustion of all carbonaceous fuels. It occurs dissolved in many mineral waters as alkaline carbonates. In solid combination, it forms the carbonate groups of minerals embracing limestones, calcite and many important ores of the metals,—iron, copper, lead, zinc, etc.

*Properties.*—Carbon dioxide is a colorless gas of pungent taste and while not supporting combustion or respiration it acts passively by excluding the proper amount of air. It has no corrosive action on metals or fabrics. The gas is heavier than air, having a sp. gr. of 1.5241 at standard temperature and pressure (0°C. and 760 mm.).

It is soluble in water which can absorb about two volumes at 32°F. and atmosphere pressure, the solubility increasing as the pressure increases and the temperature diminishes. It can be compressed to a colorless and very mobile liquid of a sp. gr. nearly that of water, viz.: 0.9474 at 0°C.; 0.8825 at 42°F.; 0.7385 at 65°F., and only 0.60 at 86°F. The liquid is slightly soluble in water and boils at  $-78.5^{\circ}\text{C.}$  ( $-108^{\circ}\text{F.}$ ) at the normal pressure of the atmosphere; at 13°F. under a pressure of 17 atmospheres (255 lb.) and at 77°F. under 66 atmospheres (about 1,000 lb. per sq. in.).

When a mixture of liquid carbon dioxide and ether is brought under the vacuum of an air-pump, the temperature drops to  $-110^{\circ}\text{C.}$  ( $-110^{\circ}\text{F.}$ ), which is sufficient to solidify the liquefied acid to a transparent ice-like mass. The latent heat of evaporation of the liquid at 0°F. is about 125 thermal units per pound, diminish-

ing very rapidly as the temperature rises and falling to 19.28 thermal units at 86°F.

The liquefaction of carbon dioxide gas was first made by Faraday as a laboratory experiment and later by Thilorier to an important amount in an apparatus which has since become classic and which perfected by Neuterer of Vienna and Bianchi, could furnish several pounds of the liquid. In a general way the principle of the apparatus is to generate the gas in a closed vessel by any well-known chemical reaction, the gas itself making the pressure required to liquefy it; in this form it is distilled from the generator into a receiver of iron or steel connected with the generator and properly cooled in a freezing mixture. The receiver, generally a cylinder capable of resisting high pressure, is provided with the proper valves and, according to its position, can furnish gas if the valve be opened, or liquid if the receiver be inverted. In the latter case, the liquid carbon dioxide escaping will vaporize instantly in the air, producing so low a temperature by the evaporation and expansion of the gas produced that a part of the liquid is solidified in the form of a snowy-white substance which may be collected in a proper receptacle as it flows from the cylinder. This "snow" can readily be kept for 12 hours or more in a woolen cloth; it gradually returns to the gaseous state, producing an intense cooling effect by the double change of state from solid to liquid and liquid to gas. Two pounds of liquid carbon dioxide can readily furnish 1 lb. of snow. Many ingenious contrivances have been devised to produce important quantities of this snow.

Carbon dioxide, being a weak acid radical, it is readily obtained in the gaseous state by the decompositions of the carbonates by a stronger acid.

*Applications and Uses.*—In the gaseous state carbonic dioxide has had for years an important use in the manufacture of beverages charged with the gas under pressure, as water, wines and the like. The apparatus formerly adopted, while well constructed for the purpose, was cumbersome, and called for special manipulations which obviously could be avoided if the gas could be supplied in a liquid form which could give out by its evaporation several hundred times its volume of gas. For many years, however, liquid carbon dioxide remained a curiosity of the laboratory, but for the last 20 years its production has become quite common, thanks to the development of the mechanical arts in general and to the advent of steel in particular, which furnished cheaply vessels capable of sustaining the great pressure generated. It was first prepared on an industrial scale in Germany by Dr. Raydt, of Hanover, who in 1879 used it for the novel purpose of floating a sunken German ironclad, the *Grosser Kurfürst*, which had been sunk by a collision in the channel. The necessary amount of gas was evolved in strong impervious canvas bags and the submerged vessel was raised to the surface. Since that time liquid carbonic dioxide has entered into the industrial practice, and in 1887 its manufacture in Berlin alone amounted to one ton daily. Notwithstanding the enormous pressure of from 800 to 1,000 lb. per sq. in. prevailing in the flasks in which it is stored, it can be safely handled, and in Europe no accident has attended its use. The receivers are of drawn or lap-welded steel cylinders, tested to a pressure of 3,000 to 3,500 lb. per sq. in. (250 atmospheres). They contain 20, 30 and 36 lb. of liquid and are filled

at a pressure of about 800 lb. The empty 20-lb. size cylinder weighs 90 lb. and measures 43 in. in height by 7 in. in diameter. The bottom is made concave and the top is drawn to a neck in which a proper screw plug is fitted. At a temperature of about 68°F. the pressure inside is 849 lb. per sq. in., and at 86°F. about 1,000 lb. per sq. in. In some tests made about a year ago by the Scotch & Irish Oxygen Co., of Glasgow, vessels of this type filled at a pressure of 1,800 lb. per sq. in. were allowed to fall 35 ft. on to iron blocks and otherwise severely treated without damage further than bending and a certain loss of shape.

One of the principal applications of liquid carbon dioxide is for the manufacture of carbonic or "soda" water and other beverages. By its use not only are the manipulations considerably simplified; but the amount of carbon dioxide introduced can be accurately regulated at pleasure. One pound of liquid carbon dioxide will produce about 8 cu. ft. of gas at atmospheric pressure, that is, over 500 times its own volume. The property of carbon dioxide not to support combustion indicates its use as a fire extinguisher in the liquid state, since in a small volume of the latter is disposed a large amount of gas, and its price, low as it has become, appears to be the only objection to its use for this purpose on a large scale. A portable apparatus containing liquid carbonic dioxide would prove very effective.

On board vessels, in case of conflagrations in the hull or elsewhere, the use of liquid carbonic dioxide would be of great value, as a large volume of gas would be immediately available and the cylinders would occupy but little room on or between decks. The great advantage of carbonic dioxide is that it does not injure the fabrics in any way. It is remarkable that its application in this direction has not become more general. It has been used with great advantage to extinguish an underground fire in a certain colliery.<sup>1</sup> The building off of the heading not having succeeded in smothering the conflagration, resource was had to liquid carbon dioxide. Ten 20-lb. cylinders of the liquid were connected with a 2-in. drain pipe having 0.75-in. branches placed at intervals of about a foot, and the flow of gas directed on the fire. The results were entirely satisfactory.

As the liquid evaporates cold is produced and the low temperature at which the gas escapes from the cylinder is in itself a favorable factor, but, as this low temperature may cause the discharge valves of the receivers to choke when the gas is generated, the cylinder, while being emptied, may be immersed in water kept lukewarm by a jet of steam, a proceeding however which is not unattended with danger.

In England and Germany liquid carbon dioxide costs 4@5c. per lb., and it is considered by Cowles that in an atmosphere containing 15% CO<sub>2</sub> flame will be extinguished. On this basis the test of carbonic dioxide for fire extinguishing purposes is about 2% per cu. yd. of space to be filled. This may appear a large figure, but in case of a fire in a mine, flooding by water involves a subsequent pumping as well as the stopping of mining operations and may amount to more than the cost of the carbon dioxide. In an ordinary fire in a town it is a question if the spoiling of goods by water would not amount to

<sup>1</sup> Abstract of a paper in *Transactions of the Federated Institute of Mining Engineers*, reproduced by the *Engineering and Mining Journal*, Vol. LXVIII., No. 6, Aug. 5, 1899.

more than the cost of liquid carbon dioxide. On a limited scale<sup>2</sup> liquid carbon dioxide has been used for cooling test pieces of rails, wheel-tires, stoves, etc., by wrapping the pieces in several thicknesses of coarse cloth, placing them in a tight and well insulated box and directing on them a jet of liquid carbon dioxide, which, by solidifying packed them in the snow thus formed. Carbon dioxide gas has been suggested as a means of preserving perishable articles in transportation in cars made air-tight by a zinc lining.<sup>3</sup> By creating an atmosphere of the gas in the cars, air,—the cause of the decay,—is excluded. In this line a relative success has been secured. Beef meat has been thus preserved for eight days in summer without change, and for 14 days with but little change; but mutton and veal would not keep. However, fruits have been sent without deterioration from California to Chicago in cars containing an atmosphere of carbonic dioxide, at a cost of \$125 per car; cylinders of liquid carbon dioxide were used to create and maintain the antiseptic atmosphere. Butter also has been preserved in the same manner. It is a question however whether this use of liquid carbon dioxide will ever be of commercial benefit.

As the gas is supplied from the cylinders at a high pressure, it has been suggested to use it to propel torpedo boats, street vehicles, locomobiles, or the like. The negative chemical properties of carbon dioxide render it particularly adapted for purposes of this kind.

Liquefied carbon dioxide is now being used for raising beer<sup>4</sup> instead of the ordinary pump. A valve is attached to the cylinder, which reduces the pressure to about 4 lb. per sq. in. or whatever pressure is required to raise the beer from the cellar to the tap. An air-tight connection is made for the top of the barrel and the pressure not only elevates the beer in good condition, but it is said to improve it as the level gets lower in the barrel. The antiseptic qualities of the gas makes its use preferable to that of the ordinary beer engine. Liquid carbon dioxide has been found advantageous in bottling beer also, and beer thus bottled matures in three days instead of three weeks.

The liquid has found a very extensive application for refrigerating purposes, either for making ice or for cooling rooms for the preservation of perishable articles,—packing-houses, abattoirs and the like; and it is now used in mechanical refrigeration in competition with ammonia, sulphur dioxide, methyl chloride, and other volatile liquids. Without describing the mode of working of the various refrigerating machines or stating the volatile liquid used, the *modus operandi* is the same; they differ only in the details of the mechanical contrivances employed to meet the special requirements of each liquid. Liquid carbon dioxide as a refrigerating agent has the advantage of requiring the smallest capacity of compressing and exhausting pump for a given amount of cold obtained, but it does this at the expense of very considerable pressure necessitating particularly strong and well-built machines. In this particular line of application objections have been raised against its use in very warm climates. There appears to be for each fluid a temperature at or above which it passes into the gaseous state no

<sup>3</sup> *Ice and Refrigeration*, Vol. VII., p. 236, and others.

<sup>4</sup> *Ibid.*, Vol. IX., p. 254.

matter to what pressure it is subjected.<sup>5</sup> This temperature is called "the critical point," and above it the fluid is considered uncondensable gas. The critical point for carbonic dioxide has been determined by Andrews at 86°F.; that is, according to our present knowledge. Above this temperature carbon dioxide can only exist in the gaseous form and cannot be liquefied by removing the latent heat of evaporation, whatever may be the pressure. This seems to be in contradiction with actual action of carbon dioxide refrigerating machines operating in the tropics at temperatures above 86°F. even as high as 94°F. These machines are stated to give fully ten times the refrigerating effect which could be expected from carbon dioxide if it were acting simply as an uncondensable gas at these temperatures. Windhausen is the authority for this statement, which is fully confirmed by other large builders of machines, over 40 being now in successful operation in the tropics or on board of refrigerating ships at temperatures above 86°F. While a detailed discussion of this question which has somewhat puzzled technical engineers and scientists is hardly in place here, it has been deemed advisable to state briefly the two sides of the question.

A scheme has been proposed to use liquid carbon dioxide as a refrigerating agent for a "pipe system" to supply cold in the same manner as heat or steam is furnished in certain cities. It consists in laying under ground special pipes, well insulated, in which the liquid would be circulated and delivered to the customers for the purpose of cooling ice-boxes and refrigerators or even of making ice for their own use. Without entering into details it can be conceived that if liquid carbon dioxide fills certain receivers at the customers' place from the distributing pipe, it can be tapped as a gas at a very low temperature in a system of coils properly disposed in the refrigerator; the evaporation in the receiver itself producing also an intense available cold and the gas resulting from the evaporation could be returned to the works to be liquefied anew after having produced the desired cooling effect, or wasted, if the carbonic dioxide could be produced as a by-product at a nominal price. Considerable capital has been invested in a certain city in the West for such a scheme; pipes were laid down and works constructed, but so far no official notice of its success has come to hand. Among possible causes of failure are the many difficulties inherent in a "pipe system" in general, which even with steam has not been particularly successful.

**Manufacture.**—Liquid carbon dioxide can be manufactured in four ways:—

- (A) Directly from the natural gas.
- (B) Indirectly from the carbon dioxide gas generated during the fermentation of liquids.
- (C) Indirectly from the gas resulting from the combustion of coke or other fuel.
- (D) Indirectly by the decomposition of the carbonates, dolomite, calcite, magnesite, and even ammonium carbonates.

Tests made by Mr. Simon Thomas<sup>6</sup> show that the liquid carbon dioxide obtained by these methods is very pure, the product from the natural gas being

<sup>5</sup> "Compend of Mechanical Refrigeration," by J. E. Siebel, and discussion of the question in *Ice and Refrigeration*, Vol. I. to XL, by sundry writers.

if anything the purest. The impurities are mainly carbon monoxide (CO) and watery vapor. The following analyses are quoted of the product obtained by the different processes:—

|                           | Vessel Content. | Residue.       |                                      |
|---------------------------|-----------------|----------------|--------------------------------------|

*Process A, Using Natural Gas.*—The conditions under which the natural gas escapes from the earth determine the particular mode of collection. The collected gas is practically pure, containing but little watery vapor. It is carried through pipes from the source of supply to a dessicating tower containing calcium chloride which frees it from moisture; an intermediate gas holder may be used to store it. From the tower it passes to the compressors and is liquefied. The product is then filtered through charcoal and stored in steel cylinders for use.

*Process B, Using Gas Collected from the Fermentation of Beer or Other Liquids.*—A description of this process, first carried out at the Guinness brewery, in 1890, is given by A. Marcet, as follows:<sup>7</sup> The quantity of carbon dioxide gas evolved during fermentation is approximately equal in weight to the alcohol produced. In breweries the rapid evolution of the gas begins in about 20 hours, and in distilleries in about 6 or 8 hours after "pitching" and for some time after the evolution is sufficiently rapid and regular to allow it to be drawn off by pumps without fear of entangling the air. If air is drawn into the compression pumps, however, it can be removed by a special release valve. For collecting the gas the ordinary parachute or "skimmer" is used having a hoisting gear, which permits it to be kept above the head of the yeast. The level of the carbonic dioxide gas in the vat is ascertained by an ordinary collodion air balloon, which floats on the upper surface of the stratum of gas. The collection is stopped as soon as the evolution of gas becomes slow. A three-stage compressor is used, the gas being pumped after the first stage (15 lb. per sq. in. compression) by passing through strong sulphuric acid water and a weak solution of potassium permanganate. To purify 100 lb. of carbon dioxide gas requires 5·5 lb. sulphuric acid, 0·75 oz. of permanganate and 0·75 oz. sodium carbonate. The pressure in the third stage reaches about 60 atmospheres; from this stage the gas passes to the condensing coils, which are cooled by a circulation of water, and is there liquefied. The intermediate collecting vessel and the receiver or drum are suspended on special balances (Sattie's), so that the attendant can see at once when they are full. The gas obtained in this way is 99·5% pure and is odorless. The cost of the liquid carbonic dioxide, including labor and interest on capital, is about £3, 10s. a ton, and in 1895 it sold at £18 a ton.

In other breweries Kuhler's method is followed,<sup>8</sup> which consists in placing over the vat when the fermentation is well started, a cover which closes it hermetically.

<sup>7</sup> *Transactions of the Institute of Brewing: Abstract in Ice and Refrigeration*, Vol. IX., No. 4, 1895.

<sup>8</sup> *Ice and Refrigeration*, Vol. IX., p. 254, 1895-1896, and others; *Génie Civil*, Vol. XXIX., No. 5, p. 75, 1896.

Pipes from this cover deliver the gas to a gas holder from which it is drawn by a pump and forced through a calcium chloride column to deprive it of its moisture. From this it is discharged under a pressure of 10 atmospheres into a desiccating vessel containing concentrated sulphuric acid. From the desiccator the gas is forced into a water-cooled coil from which a second compressor forces it through a cotton filter, discharging it under a pressure of 70 atmospheres into a steel receiver immersed in cold water. One hectoliter of beer (about 26.5 gal.) will yield 1.5 kg. (3.6 lb.) of liquefied gas.

*Process C, Using Gases from the Combustion of Fuel.*—At the Da Road Works, Old Fords, England, the process is carried on as follows:<sup>9</sup> The carbon dioxide gas is produced by the combustion of coke in furnaces having two boilers or vats which form a part of the apparatus, the waste gases are passed through scrubbers having a continuous circulation of potash lye, which absorbs the carbon dioxide. This solution then passes to the boilers or vats, where the absorbed carbon dioxide gas is disengaged by heat and subsequently collected, purified, and sent to the compressors. The potash lye thus deprived of its carbon dioxide gas is returned to the scrubbers for further use. The sulphur contained in the coke is transformed into sulphur dioxide by the combustion, and, as the gas would combine with part of the potash solution and waste it, the mixed gases, carbon dioxide, and sulphur dioxide, as they leave the furnace, are washed first in hot and then in cold water, which readily dissolves the sulphur dioxide to the extent of about 35 volumes, the carbon dioxide gas being only sparingly soluble. To wash the waste gases they are pumped into special vessels containing small fragments of marble through which water circulates, first hot in one vessel, then cold in the other; before reaching the washers the hot furnace gases are utilized to heat the wash water by circulation through coils. The gases thus washed and deprived of sulphur dioxide and other impurities are pumped to the absorbing towers, filled with coarse fragments of coke over which flows a continuous supply of lye solution. This solution absorbs the carbon dioxide gas and is collected in a special reservoir from which it is pumped to the boilers or vats, and there deprived of its carbon dioxide gas content. The normal pressure in the boilers is about 5 lb. per sq. in. The purified carbon dioxide gas is collected in a gas holder which supplies water-jacketed compressors of the three-stage vertical type, operated by a 20-H.P. engine. The first compressor is of the double-acting type and compresses the gas to 20 lb. per sq. in., discharging it into a purifier, where the last trace of moisture is removed by calcium chloride. The second compressor, single acting, delivers the gas at 125 lb. per sq. in. to a series of water-cooled coils before it reaches the third compressor, a single-acting one also, where it is compressed to 70 atmospheres (about 1,000 lb. per sq. in.) and liquefied in a properly cooled condenser. These plants have a capacity of 10 tons of liquid carbon dioxide per day.

*Process D, Using Gas Produced by the Decomposition of Carbonates.*—In the Osborne process bituminous coal is used instead of coke, and the distillation is made at a low temperature, furnishing maximum amounts of coal-tar and am-

<sup>9</sup> *London Engineering*, Oct. 21 1899; reproduced by *Génie Civil and Engineering and Mining Journal*, Oct. 21, 1899.

moniacal products. The illuminating and fuel gas produced is utilized to operate the gas engines for the compressors as well as to supply all the power required in the works. The coke remaining in the retorts as the ultimate product of the distillation of the bituminous coal, is used for making water-gas for calcining the limestone (calcite) in closed retorts. These retorts are of a spherical construction and superheated steam is added, which expels all the available carbon dioxide in the calcite. The gaseous product is washed and deprived of moisture before being liquefied by the compressors. The chemistry of the process has been fully endorsed by Prof. B. Stillman, who claims: that the distillation of the soft coal can readily furnish a producer gas of a heating power of 165 thermal units per cu. ft.; that the price of the by-products,—tar and ammonia liquids,—will offset to a large extent the cost of generating the gas; that the use of superheated steam in the calcite retorts will secure a maximum yield of carbon dioxide. This process was used in connection with the pipe line referred to above, and it was estimated that, with coal at \$3 a ton, calcite at \$2, ammonia liquors at 7c. per lb., coal tar at 5c. per lb., and pure calcined lime at \$5 per ton, the liquid carbon dioxide could be furnished to customers at \$6 per ton; in fact, as far as cost is concerned, the liquefied gas itself could be considered a by-product—at least it was so stated.

The calcination of limestone, either dolomite or calcite, can be accomplished in intermittent kilns, in kilns with alternate layers of fuel and stone, in compartment ovens (Hofman), or in kilns similar in construction to ordinary brick kilns. In all cases the carbon dioxide gas, more or less impure, is collected, purified and condensed to the liquid state by compressors, as described above. The heat necessary for the decomposition of the carbonate is furnished in many plants by fuel charged with the limestone, but special contrivances have been devised by which the heat can be supplied by producer gas or mineral oils. Kilns or ovens using gaseous fuel give the purest product.

The kiln of Vigreux & Desclosages is used considerably in France.<sup>10</sup> It is circular in shape, and charged with a closed top, like a blast-furnace. Around the circumference are arranged inlets for the producer gas which is burnt by admissions of air in special burners. It is claimed that the limestone is completely calcined after one and a half hours in the zone of heat where the temperature reaches 1,000 to 1,100°C. (1,800 to 2,000°F.). The calcined product is withdrawn every hour or so; at the same time a fresh quantity of stone is charged at the top. The average production for one year of operations was 1,000 kg. of calcined lime for 208 kg. of coke from gas works. The gases at top (carbon dioxide and nitrogen) are collected as in the blast furnace for iron and an analysis gave the following composition by volume: CO<sub>2</sub>, 34%; O, 0.5%; CO, 0.24%; N, 65.25%. The difference of specific gravity of nitrogen (less than 1) and of gaseous carbon dioxide (1.5) allows of a ready separation in a gas holder.

Of a still greater industrial importance is the use of magnesite (magnesium carbonate) which yields magnesia, the carbon dioxide gas being obtained as a by-product. Magnesia is the basis of the magnesite bricks used largely for

---

<sup>10</sup> *Génie Civil*, No. 7, Vol. XXXVI., p. 107.

special requirement in the construction of metallurgical furnaces. Calcined magnesite is worth from \$15@ \$19 per ton, while lime is worth about \$5. While magnesite occurs in many parts of California, but from 2,000 to 3,000 tons a year reaches the market from this source, owing to the cost of transportation. In 1900, 28,000 metric tons of magnesite was imported from Europe, some from Styria, but principally from Eubœa, Greece. Good Styrian magnesite contains from 90 to 95%  $\text{MgCO}_3$ , 1 to 2%  $\text{SiO}_2$ , 0.5 to 2%  $\text{CaCO}_3$  and  $\text{FeO}$  up to 6%. The Eubœan magnesite averages 95 to 98%  $\text{MgCO}_3$ , and is generally free from iron oxide and silica. One hundred pounds of pure magnesium carbonate will yield 47.6 lb.  $\text{MgO}$  and 52.4 lb.  $\text{CO}_2$ , while the same amount of pure calcite will yield only 44%  $\text{CO}_2$ . In manufacturing liquid carbon dioxide from magnesite, the following method is used: The furnaces are circular in shape and mounted on columns. They are 10 ft. in diameter, 15 ft. high above the columns and have a total height of 23 or 24 ft. Inside the furnace and projecting a little from the masonry at top and bottom are seven vertical iron pipes, 12-in. inside diameter, and open at both ends. The magnesite, crushed to egg size, is charged in these pipes, their lower ends being previously hermetically plugged after charging; the pipes are closed at the top in a similar way. The furnace is heated with gas fuel (mineral oil burned in proper burners), inlets being supplied for the heating gases and outlets for the products of the combustion. The pipes are connected at their upper ends with a common 6-in. pipe which collects the carbon dioxide gas resulting from the calcination of the carbonate. The charging is made from a small wagon provided with a chute which circulates on a movable platform car allowing the different furnaces to be successively charged. One furnace is generally charged in the morning and the calcination proceeds for 20 hours, which is sufficient to expel practically all of the combined carbon dioxide. The stone when discharged from the retorts contains 95 to 96%  $\text{MgO}$ . If calcined at a comparatively low temperature the calcined product will absorb water and carbon dioxide after a few days, analyzing then only 94%  $\text{MgO}$ . The carbon dioxide gas as it leaves the retorts circulates through water-cooled coils, where its temperature is lowered and then passes to the gas holder of a capacity sufficient for 3,000 or 3,500 lb. of gaseous carbon dioxide (approximating 30,000 cu. ft.). From the gas holder the gas is purified and delivered to the compressors, which liquefy it and deliver it to the steel cylinders. Two men can fill 20 drums in an hour. There are many other arrangements used to calcine magnesite or other carbonates, but the method described above will suffice for the purpose of illustration.

#### THE DEVELOPMENT OF THE LIQUEFIED CARBONIC ACID GAS INDUSTRY.

*United States.*—(By J. C. Minor, Jr.)—There are 19 companies engaged in the liquefaction of carbonic acid gas in the United States and two in Canada, whose names and addresses are given in the table on the following page.

At six of these plants the gas is prepared directly from the natural carbonic acid gas arising from mineral springs. Eight of the plants obtain their gas from the fermentation of liquids, nine from the combustion of coke, and twelve from the decomposition of carbonates, either by heat or by wet processes.

| Name of Company.                             | Address.                                                                                             |

Saratoga Springs, N. Y., is the only place in the United States at which natural carbon dioxide gas is liquefied. For over a hundred years several carbonated saline springs have been flowing naturally to the surface under considerable pressure due to the contained gas, notably the High Rock and the Hathorn Springs. The volume of water and gas delivered through these natural crevices is quite small, but by drilling many springs to depths of between 100 and 600 ft. Saratoga has become most prominent as a watering place.

In geologic occurrence all of the springs are located along the line of a fault passing through the town from the northeast to the southwest. The wells are generally drilled 6 in. in diameter, and extend down and through the strata of the Hudson river shale until the Trenton limestone is reached. Wells that have been drilled through the limestone formation as far as the underlying Potsdam sandstone have always been weakened in force. About 20 springs in the village are used for drinking purposes, while those used for gas production, about 20 in number, also, are situated along the line of the fault 1.5 miles to the southwest. The latter are of greater output in gas and water than those in the village, the production being frequently aided by pumps. The average spring used for producing carbon dioxide gas will yield about 400 lb. of gas per 24 hours, with a flow of water from 5 to 6 gal. per minute. In a few cases the flow of the spring has been more than quadrupled by pumping. The gas is separated from the water at the mouth of the spring and is piped to the gas holder from which it is subsequently drawn off and purified by passing it through dryers and purifiers.

The natural carbon dioxide gas contains about 0.5% of air, a much less quantity than occurs in gas produced by other processes. A trace of hydrogen sulphide is frequently found, although several of the companies make no effort to remove this impurity.

It is obvious that the cost of manufacture of liquefied carbonic acid gas is less at Saratoga than by processes carried on elsewhere, but because of the geologic conditions, the supply of gas is limited and the local companies can hardly become a controlling factor in this industry. As late as 10 years ago, the ordinary price of carbon dioxide gas was about 20c. per pound, and even at this price its greater

convenience led to its rapid adoption, principally in the manufacture of carbonated beverages. The price is determined more by the length of time that the steel cylinders are kept by a customer than by any other factor. At the present time it ranges from 5 to 12c. per lb. with an average of about 7c. in the supply of all classes of trade.

The large consumer who prefers to make his own carbon dioxide gas rather than to purchase the liquefied product, and whose consumption may, roughly speaking, average 10,000 lb. a year, can manufacture gas from a carbonate for about 3.5c. per lb. including waste and labor.

It has been impossible to obtain exact figures of production, but the estimate for the United States and Canada during 1901 of 14,000 short tons of liquefied carbon dioxide gas is substantially correct. On the surface this does not indicate a very large industry, nor is it when measured by the amount of money invested. The total value of the cylinders owned in the United States by all the companies is estimated at \$2,000,000. The magnitude of the field of operation is best shown however in the fact that the amount of gas manufactured in 1901 in the United States was sufficient to carbonate over 150,000,000 gal. of soda water, a use for which the greater part of the liquefied gas was consumed.

*Germany.*—The development of the liquid carbon dioxide industry has attained great prominence in Germany,<sup>11</sup> and 29 firms owning 39 carbon dioxide works have formed the Deutsche Kohlen Actien Gesellschaft. This does not include however the largest independent works, which alone supply the entire German demand.

The branch of the industry in Württemberg threatens the manufacture of carbon dioxide gas from coke or lime as the natural gas wells up from the earth in the valley of Eyachthal on the upper Neckar, and can be collected at a nominal cost. One firm in this locality, with a capital of \$500,000, possesses 30,000 steel drums, and to avoid freight on them extremely strong iron tank-wagons each of 10 tons' capacity are used to transport the liquid carbon dioxide in bulk to Zurich, Berlin and Vienna, where the steel drums are charged for local distribution. In 1898, 2,950 tons of liquid carbon dioxide valued at \$150,000 were exported from Germany, and in 1900 the total reported production of the world amounted to 38,000 tons, distributed as follows:—

| Countries.           | Number of Works. | Production in Metric Tons. |
|----------------------|------------------|----------------------------|
| Germany.....         | 42               | 16,000                     |
| France.....          | 15               | 7,000                      |
| Austria-Hungary..... | 12               | 1,800                      |
| United States.....   | 18               | 14,000                     |

In Germany this industry has increased very rapidly during the last 15 years, as shown by the following figures: Production in 1884 amounted to 122 metric tons; in 1891, 3,000 metric tons; in 1897, 11,000 metric tons; and in 1900, 16,000 metric tons. Of the last named amount, Berlin consumes no less than 1,800 tons, which corresponds to an annual consumption of 2 lb. of liquid carbon dioxide gas per capita of the population in this city. Two-thirds of the German works produce the liquefied product from the natural gas emanating from

<sup>11</sup> British Consular Reports, Nos 561 and 2671, 1901.

springs. The remaining third employ chemical methods to generate the initial gas. The amount of capital invested in this industry in Germany is estimated at \$5,000,000, and to this should be added the value of 700,000 steel drums and 30 steel tank-wagons, making in all, \$9,000,000. Fifteen years ago the price of the liquid was about 25c. per lb.; now it has decreased to about 4c. per lb. The export from Germany of liquid carbon dioxide in 1890 amounted to 4,000 tons, valued at \$1,500,000, which diminished to 3,618 tons in 1899.

## RECENT PROGRESS IN THE WETHERILL SYSTEM OF MAGNETIC SEPARATION.

BY H. A. J. WILKENS.

THE Wetherill system of magnetic separation has been so frequently described in the various technical publications that the principles upon which it is based, as well as the results obtained by its use, are fairly well known to the mining and metallurgical professions. Briefly stated, John Price Wetherill, the inventor of the system, was the first to realize the commercial possibilities of utilizing the slight magnetic qualities inherent in a large number of ores and minerals and to devise a practical machine to separate such materials by means of a highly condensed magnetic field.

Broad patents<sup>1</sup> covering the process as well as various types of machines were granted in the United States and are now owned by the Wetherill Separating Co., of New York, and similar patents were granted in many foreign countries, which are now under the control of a German syndicate represented by the Metallurgische Gesellschaft, of Frankfort-on-Main, Germany. The broad process patents have been sustained in the German courts, a suit for non-validity having been brought by the Mechernicher Bergwerk-Aktien Verein. From the decision of the German Reichs Gericht, which is printed in full in the *Engineering and Mining Journal*, November 17, 1900, the following extract shows the view taken by the Court:—

“The arguments in support of the decision are stated as follows: ‘For the consideration of the question, whether the process characterized by the first claim was new and patentable at the time of the application, it is immaterial that long before the date of application the existence of weakly magnetic and non-magnetic minerals was known, besides the strongly magnetic ores; likewise the classification given by M. Faraday, 60 years ago dividing all substances into two classes, paramagnetic and diamagnetic, since constituting a common acquisition of scientific and technical knowledge, is by no means prejudicial to the patent.

“The Application Department knowing these premises has allowed the first claim on the well-justified ground that Wetherill was the first to recognize the applicability of these known facts to the magnetic separation of weakly magnetic substances, without first transforming them into the strongly magnetic state

---

and to demonstrate their separation from non-magnetic substances upon a commercial scale.'"

**Apparatus.**—The machines devised by Mr. Wetherill have passed through a period of evolution, the original ones having been gradually superseded by others which, although operating on the same general principle show considerable improvement in their mechanical features. The main credit for the improvements is due to Mr. Lewis G. Rowand, who has been connected with the Wetherill process in this country almost since its inception, and to Mr. Max Schiechel, who has charge of the operations of the company exploiting the foreign patents.

In general the machines used can be divided into two types:—

1. Separators in which the magnetic particles are lifted away from the raw material brought to the magnets, and mechanically carried away from the non-magnetic products, and—
2. Separators in which the course of the moving ore is influenced magnetically

FIG. 1.

FIG. 2.

MAGNETIC SEPARATORS OF THE FIRST TYPE.

in such a way as to carry the various ingredients in separate directions, according to their magnetic permeability.

The most highly developed machine of the first class is illustrated in Figs. 1 and 2, the former showing the general principle of the operation, and the latter a complete working machine with an 18-ft. feed-belt and three pairs of magnets. Referring to Fig. 1; *M* and *M'* are two magnets so arranged that the pointed poles *P*, *P'* of the upper magnet are placed close to and above the flat pole pieces *L* and *L'* of the lower magnet. Passing through the magnetic field produced between these pole points is a rubber feed-belt *F*, which is carried by the pulleys *D* and *D'* and receives the continuous feed of ore from the hopper *H* by means of the feed-roll *R*. The two take-off belts *T* and *T'* move at right angles to the feed-belts along the bottom of the upper pole points.

The machine operates as follows: As soon as the material on the feed-belt *F* arrives below the pole point *P*, the magnetic materials in the mixture are lifted to this point and are held against the lower side of the take-off belt *T*, which carries them along the pole point until they are removed from the field and dropped through a suitable chute into a receptacle *Y*. Meanwhile the material

remaining on the feed-belt has been brought to the second pole point  $P^1$  of the magnet  $M$  where the operation is repeated and the remaining magnetic materials are removed from the field and dropped through suitable chutes into receptacle  $Y^1$ . The non-magnetic products are finally carried by the feed-belt  $F$  into the receptacle  $Z$ . In practice it is often found advisable to make a series of magnetic products, and machines have been built of this type with two or three pairs of magnets placed in series across the same feed-belt. As a rule these pairs of magnets are made of gradually increasing strength or the strength of the successive magnetic fields is increased by the amount of current passed through the magnetic coils or by gradually decreasing the distance between the upper and lower pole point. On the three-pair magnetic machine, six magnetic products and one non-magnetic product will be produced in this manner, each succeeding

FIG. 3.—MAGNETIC SEPARATOR OF THE SECOND TYPE.

magnetic product being composed of material of a somewhat slighter magnetic permeability than the preceding one.

Fig. 3 shows a machine used in Europe and in Australia for ores which are very slightly magnetic. In this are three magnetic coils and pole pieces. The pole point  $P$ , which does the active work of separation, is of opposite polarity to the points  $P^1$  and  $P^2$ . Around the pole point  $P$  and actuated by the pulley  $D$  is a thin linen belt  $F$  on which the ore is fed from the hopper  $H$  by means of the feed roller  $R$ . When the material reaches the pole point  $P$ , the magnetic particles adhere to the feed-belt  $F$  as it rounds the point, while the non-magnetic materials are thrown off by the momentum imparted to them by the moving belt. By means of the shutter  $S$ , which can be adjusted with a small set-screw, the two grades of ore are accurately separated. This machine operates successfully on materials of very slight magnetic permeability at the expense of a comparatively low magnetic current, it being only necessary to hold the material for a moment

the non-magnetic material is dropped into the receptacle *Z* being separated from the magnetic material by the shutter *S*<sup>1</sup>. The magnetic particles are carried beyond the shutter *S*<sup>1</sup> in a horizontal direction and fall into the receptacle *Y* or *Y*<sup>1</sup>, according to their magnetic permeability. In operation the take-off belt *T* is needed more to keep the pole points clean than to hold and carry the ore.

The machine illustrated in Figs. 1 and 2 is being used exclusively in the United States. Although its first cost is considerable on account of the high power magnets employed and the strong frame and running gear, experience under varying conditions has shown that it is warranted, as continuous running and a minimum expenditure for repairs is guaranteed. The standard type placed upon the market by the Wetherill Separating Co. is operated with an 18-in. feed-belt and with from one to three pairs of magnets which are wound as a rule with 30,000, 60,000, and 100,000 ampere turns. The current employed is 110 volts and for a three-pair magnet machine the maximum amperage for the magnets is respectively 5, 15, and 30. The power necessary to actuate the running parts of the machine does not exceed 0.5 H.P. The power necessary to produce the current for the magnets varies from 1 to 7 H.P., depending entirely upon the magnetic permeability of the ore which is separated and the number of pairs of magnets on the machine. The capacity of the machine varies from 0.3 ton to 6 tons per hour, and is estimated by the size and magnetic permeability of the material treated. It is greatest on coarse sizes of more highly magnetic material and least on fine sizes which are very slightly magnetic.

Applications.—In general it may be stated that all minerals containing iron or manganese are susceptible to separation by the Wetherill process. The magnetic qualities of minerals of this character, however, are not directly proportionate to the quantity of these elements contained, but seem to depend more upon their combination. It is a curious fact that almost all dolomite and even limestone, which is found adjacent to ore bodies and which may contain barely a trace of iron or manganese, will be magnetic, while pure iron pyrite,  $\text{FeS}_2$ , appears to show no paramagnetic properties whatever. On the other hand, there are some of the rarer metals, as chromium and cerium, which show sufficient magnetic properties to enable ores containing large quantities of them to be handled on the Wetherill machines. To the presence of cerium in monazite must be attributed the ability to separate this ore from quartz and other non-magnetic materials. It has been found also that minerals from different localities, although of practically the same chemical composition, will vary in their magnetic attractability, so that in most cases an actual experimental treatment is necessary in order to determine whether an ore can be successfully treated by the Wetherill process or not. Thus, a few zinc blendes, more especially those of the darker varieties, will be comparatively highly magnetic, while others are very much less so and may not be susceptible to magnetic treatment.

Apart from the magnetic qualities of the minerals, the successful treatment of an ore by the Wetherill system is predicated upon the same general conditions which govern mechanical separation in that the ore must be crushed sufficiently fine to bring about a breaking apart of the separate ingredients. It is practically impossible to treat some ores on account of the extremely fine dissemination of

the ingredients. The treatment of dust is impracticable magnetically for the same reasons which have rendered it impossible to treat fine slimes either by water or air separation. When the particles become so small in size that the effect of gravity is *nil*, a satisfactory treatment either in air or in water becomes impossible, and despite the claims of various inventors and manufacturers I have as yet failed to find a concentrating machine which will successfully treat material below 300-mesh size either in air or water.

Sizing is as advantageous in the Wetherill process as it is in all other methods of mechanical separation. Various devices have been designed and operated for utilizing a highly condensed magnetic field for separating ore in water, but the scope of magnetic separation is apparently confined to the treatment of dry material. A dry treatment presents advantages in crushing and sizing, although the dust originating in dry mills is at times a decided disadvantage and as most ores from the mines must previously be passed through a dryer, the cost of treatment is thereby increased.

The Wetherill machines in the United States handle ore with a maximum coarseness of 8-mesh, and, while it is rare that minerals are so coarsely disseminated as to warrant crushing to larger size, the Wetherill principle can be readily adapted for material as coarse as 0.5-mesh.

The following list is composed of some of the combinations of minerals which have been successfully treated by the Wetherill process. In most cases two or three magnetic products consisting of different minerals are made. A large number of the minerals which it has been possible to separate magnetically are so similar in specific gravity that their separation by gravity machines is impossible. In this list the magnetic minerals of each combination are given in the order of their permeability, the product mentioned last being in each case the non-magnetic tails. A few minerals, as zinc blende, for instance, occur sometimes as the magnetic and sometimes as the non-magnetic portion, due to the variation of the magnetic permeability. Resin blende is non-magnetic, while some of the black blendes are quite highly so. In other instances the associated mineral is more magnetic, as is the case with spathic iron and blende; the former being withdrawn, while the latter is left as non-magnetic tails, even though it possesses magnetic permeability.

The following results obtained by the Wetherill system of magnetic separation have been selected at random from several thousand tests made on various ores.

*Copper Ore from Mexico.*—This ore was a product from a wet concentrating mill, and consisted of copper pyrite, bornite and garnet containing 6.3% Cu. The separation gave 70% of garnet, containing 0.3% Cu, and 30% of a copper product containing 19.8% Cu, representing a yield in copper of 96.6%.

*Spathic Iron and Zinc Blende from the Siegerland, Germany.*—This material was a by-product of the wet concentrating mills, and consisted of a mixture of spathic iron ore and zinc blende, the original ore assaying 20% Zn. The magnetic separation gave 68.4% of spathic iron with 5.45% Zn, 31.6% of zinc blende with 53.46% Zn, representing a yield in zinc of 82%.

*Tin Ore from Spain.*—This material was produced by a wet separation, and contained about 48.5% Sn and 22.5%  $WO_3$ , the latter being present as wolframite. The following results were obtained: 30.7% of wolframite, containing 0.8% Sn and 73.2%  $WO_3$ ; 68.5% of tin ore, containing 70.5% Sn and 1.1%  $WO_3$ , representing a yield in wolframite of 97% and a yield in tin of 98.5%.

*Spanish Copper Ore.*—This ore consisted of copper glance, malachite, and azurite, with a dolomite gangue, and averaged 2.9% Cu. The following products were obtained: 12.6% of copper ore, containing 17.2% Cu; 85.4% of gangue, containing 0.75% Cu, representing a yield of 75.5% of the copper in the raw material.

*Australian Tailings.*—This raw material was a by-product in the wet concentration of the Broken Hill sulphide ores, and assayed 30.08% Zn, 8.68% Pb, and 10.09 oz. Ag. The following products were obtained: 26% of a garnet product, containing 10% Zn, 2.9% Pb, and 5.48 oz. silver per ton; 54.5% of a zinc product containing 48.1% Zn, 6.7% Pb, and 12.58 oz. silver per ton; 19.5% in weight of a lead-quartz product, containing 8.6% Zn, 22% Pb, and 14.52 oz. silver per ton; a concentration representing a zinc yield of 89.2%.

The Wetherill process and machines are in commercial operation at the following foreign plants: In Germany, at the Gesellschaft des Emser-Blei & Silberwerks, Ems; the Bensberg Gladbacher Bergwerks & Huetten-Actien-Gesellschaft "Berzelius" Gladbach; the Silber & Bleibergwerk "Friedrichsseggen," Friedrichsseggen a/Lahn; and the Gewerkschaften Lohmannsfeld & Peterszeche, Duesseldorf, Lohmannsfeld, Neunkirchen, Rbs. Arnsberg. The operations are confined to the separation of spathic iron and zinc blende. Previous to the introduction of the Wetherill process the ores at these plants were roasted in order to change the iron carbonate to magnetic iron oxide, which was afterward removed by some of the older forms of magnetic separators. The direct treatment of this ore has not only proved cheaper on account of avoiding the cost of roasting, but the resultant products have also been of much higher grade. At the Actien-Gesellschaft fuer Zink-Industrie, Hamborn, Rheinland, the Wetherill process is used for separating a mixture of pyrite and blende; the ore is roasted before being treated on the machines, the roasted pyrite being the product removed magnetically.

In Denmark, at Copenhagen, the Oresunds Chemiske Fabriker has several machines installed for the separation of cryolite, spathic iron and copper pyrite, the latter two being magnetically removed from the former.

the ingredients. The treatment of dust is impracticable for the same reasons which have rendered it impossible to treat wolframite and tin ore by air separation. When the particles become so small that gravity is nil, a satisfactory treatment either in a shaft or by air separation is not possible.

At the Schacht Stal is operating on iron ore and despite the claims of various inventors has failed to find a concentrating machine suitable for removing the garnet, olivine and

low 300-mesh size either in air or water. The Beers Consolidated Mine, Ltd., a

Sizing is as advantageous in the concentrates from the washers of mechanical separation. Various Australian Metal Co. has 55 machines in for utilizing a highly condensed Hill sulphide ores separating both garnet

the scope of magnetic separation for foreign countries is located at the material. A dry treatment of dust originating in the mines is thereby increased. At Kalk, near Cologne, Germany. At this plant machines are installed as well as apparatus for crushing, separation, etc., which might be used to advantage in the Wetherill process.

The Wetherill process, mentioned above, there are a number of plants in course of construction for the separation of pyritic blende, adapted for

The following is the largest application of the Wetherill process has been in the United States the separation of the Franklinite ores in Sussex County, three or four plants having capacities of 500 tons and 1,000 tons per day respectively: the former is not in operation at present. At Franklin Furnace, N. J., are two plants having capacities of 500 tons and 1,000 tons per day respectively: the former is not in operation at present. The larger plant has handled as much as 900 tons in 12 hours over 17 machines of the Rowand type each equipped with three pairs of magnets. The cost of treating raw material has been as low as 38c. per ton in the most favorable month of 1901, including crushing, sizing, cooling, magnetic separation, jigging of the non-magnetic tails, drying of the jigged concentrates, and loading them on cars for shipment. The general scheme of the separation has been described at some length by Mr. John Price Wetherill,<sup>2</sup> although since this was written the methods of crushing and handling the material and the type of the magnetic separators have been largely improved. In all about 180,000 tons of ore were treated magnetically by the Wetherill process at Franklin Furnace during the year 1901.

At the Pride of the West mine, Washington Camp, Ariz., six magnetic separators of the Rowand type have been in operation on a mixture of copper pyrite, zinc blende, galena, garnet and quartz. Four of the separators remove roasted copper pyrite from a mixture of blende, garnet, galena, etc., and two of them which are of higher magnetic power are used for treating the non-magnetic tails from the above operation, removing magnetically garnet first and then zinc blende, the latter on account of a very slight admixture of iron being sufficiently magnetic to be removed in the powerful field of the machine. The galena is subsequently separated from the non-magnetic mixture of galena, quartz, limestone and calcite by means of Wilfley tables.

At the Warren mine, Warren, N. H., the process has been in operation since

<sup>2</sup> Engineering and Mining Journal, July 17, 1897.

of complex nature carrying galena, zinc blende, copper pyrite, and quartz. The ore is first concentrated on jigs to remove as much waste as possible; it is then slightly roasted and passed over Wilfley tables, which gives the following products: First, magnetic pyrite, hematite and oxidized pyrite; second, oxidized copper pyrite; third, galena and quartz. The non-magnetic pyrite, hematite and quartz are subsequently separated by dry jigging. At the Wetherill plant, at Mineville, N. Y., the Wetherill process is used for separating apatite and hornblende, this product is separated from the Wenstroem machines, which concentrate the magnetite. At present but one machine of the Rowand type is installed, several others, however, will be in operation shortly to handle the increased output of the main separating plant.

The Corundum Mining & Manufacturing Co., of Tree, Ga., will use the Wetherill process for the separation of garnet from corundum, which is produced by the wet concentration of the corundum-bearing granite.

The Colorado Zinc Co. uses the Wetherill process for separating zinc blende from pyrite at its plant in Denver, Colo. One of its main sources of supply is ore from the White Quail group of mines at Kokomo, Colo., which consists of gold-bearing pyrite with an admixture of zinc blende and a small amount of galena. This ore is first concentrated on Wilfley tables, producing a lead-iron concentrate and tails consisting of pyrite and zinc blende, the latter is dried and passed over Wetherill machines to remove magnetically the raw blende.

A similar plant is operated by Wilfley & Byron at Kokomo, Colo., for the treatment of ores of the same character.

The Empire Zinc Co., of Colo., has installed a Wetherill machine of the Rowand type at its plant at Cañon City, to treat miscellaneous ores either raw or after roasting, for the separation of zinc blende from galena and pyrite.

Messrs. Hulss & Kithil are installing a plant at Ellenboro, N. C., for the purpose of cleaning monazite sand, which is produced in the sluicing operations and consists of menaccanite, garnet, monazite, quartz and other gangue. The materials are removed by the Wetherill machines in the order stated above, the quartz remaining as the non-magnetic ingredient.

The main testing plant of the Wetherill Separating Co. is located at the corner of Ferguson and Clover Streets, Newark, N. J., and is equipped with appliances for testing any quantity of ore.

There are smaller machines installed for testing ores at the laboratories and testing plants of Henry E. Wood, Denver, Colo.; The Kootenay Ore Co., Ltd., Kaslo, B. C.; the School of Mines, Kingston, Ont.; the School of Mines, McGill University, Montreal, and the United States Geological Survey, Washington, D. C.

Bituminous coal, \$0.53 per ton in Canada and \$0.67 per long ton in the United States. (7) Copper of fin 15.00 pes.; in bars and ingots, 27.00 pes.; in sheets and rails, 42.00 pes. per 100 k. (8) Plates, sheets and wires 5 mm. in section, \$4.06 per 100 kg. (9) Bars only. Copper sheets and plates, \$0.15 per kg. (10) Unrefined. (11) purpose of being wrought, \$0.595 per 100 k. (12) Rods, plates and bars more than 7 mm. in section. Material in section, \$1.35; less than 5 mm., \$1.74. (13) Bars and rods more than 0.25 in. in section. Bars and rods 0.25 in. in section, \$0.333. (14) Sheets more than 1 mm. thick. (15) Plates more than 3 mm. thick, 12.55 pes. (16) Plates more than 3 mm. thick, \$0.904. (17) Duty varies from \$0.003 to \$0.047 per lb. (18) Plates less than 6 mm. thick. (19) more than 15 mm. thick. (20) Plates more than 55 cm. in length or 40 cm. in breadth, \$0.07. (21) Containing 25 g. silver per 100 kg. (22) Less than 50% Mn, \$0.40 per ton. (23) Nickel anodes. (24) Can be imported only permission. (25) Duty per 100 lb. in package. Salt in bulk pays \$0.06 per 100 lb. (26) Duty per kg. of refined crude salt. Refined salt pays \$0.5848 per 100 kg. (28) Per 100 lb. salt in package. Salt in bulk pays \$0.08 per 100 lb. (29) Unrefined. (30) exceeding 1.38 sp. gr. (32) Coarse wares.

## THE MINING STOCK EXCHANGES IN 1901.

THE tables on the following pages give a résumé of the business done during the past year on the leading exchanges of the United States and Europe. On the whole the year's record was a good one, although a general tendency toward lower values was in evidence, which may be regarded as a logical consequence of the inflated and fictitious quotations that ruled for many stocks in 1900.

### THE BOSTON MINING STOCK MARKET IN 1901.

The formation of the Amalgamated Copper Co., which absorbed the Boston & Montana and Butte & Boston mines, has detracted largely from the prestige once held by Boston as a center of copper mining speculation. While Amalgamated stock is still dealt in to a large extent there, the offices of the company and the financial management are located in New York, which is now the speculative center.

The most prominent feature in regard to the year's quotations was the decline in the shares of the leading mining companies. An average for the year shows a falling off of about \$50 from the top prices, which in the aggregate represents a loss of about \$250,000,000. Nearly one-half of this amount was represented by the depreciation in Amalgamated shares, the remainder being contributed by other companies mostly engaged in copper mining. Calumet & Hecla fell as low as \$535, a decline of \$325 from the highest quotation. It is probable that many of the new mining companies which were floated during the copper "boom" will have to close down in the near future if the low prices for copper should continue.

### THE COLORADO SPRINGS MINING STOCK MARKET IN 1901.

The value of the shares dealt in during 1901 was about \$20,400,000. The records show important fluctuations in some of the leading stocks, such as Portland, Elkton, Isabella, and Jack Pot, in which a downward trend was noticeable. Portland fluctuated from \$3.50 in January to \$2.75 in December, and Elkton sold off from \$1.90 at the opening of the year to \$1.39 in December. Isabella varied between \$0.77 and \$0.34. The shares of El Paso and a few others were stronger in the latter part of the year than in the opening months.

### FLUCTUATIONS IN MINING STOCKS AT BOSTON DURING 1901.

## THE NEW YORK MINING STOCK MARKET IN 1901.

The market was characterized by wide fluctuations with downward tendencies. Copper was the chief feature, and the dealings in Amalgamated formed a large part of the total transactions. The course of this stock has had few parallels on the exchange in recent years. From the low price of \$83.75 in January, it rose

c., copper; g., gold; l., iron; l., lead; q., quicksilver; s., silver.

steadily until June, when the high mark of \$130 was reached, and then declined rapidly, closing at \$60-50. The reasons given for the falling off in values were the unsettled conditions in Montana owing to the pending legal suits against the company, the reduction of the dividend-rate, and the cut in copper prices. That the stock should sell at the highest point of the year shortly before the dividend-rate

the payment of good dividends. Horn Silver, also of Utah, was strong, selling at higher prices than in 1900, and advancing to \$2.25 in October. The dividends this year, amounting to \$72,000, are the largest since 1898. Standard Consolidated Gold, of California, has been favored by the continuance of the 10-cent quarterly dividends. The extreme prices were \$4.35 in February and \$2.65 in August. Brunswick suffered from assessments amounting to 8c. per share, breaking the market from 29c. in March to 6c. in October. Cripple Creek, Colo., stocks were bought chiefly for investment. Portland, which pays 24% annually on its capital of \$3,000,000, is closely held, and the small sales made were at \$3.35 in January, and \$2.30 in March. Elkton, a 13% dividend stock, has fluctuated in price owing to the heavy flow of water in the mine, early in the year, and to the uncovering of a rich chimney of ore in October, which resulted in the payment of an increased quarterly dividend. Isabella was capricious, owing to manipulation in the Western market. Only one quarterly dividend was paid in 1901, as work in the lower levels of the property proved unprofitable; its future depends upon the development of new territory. In February 82c. was paid for the stock, but in December it broke to 30c., with few bids in the market.

The Leadville stocks were handled principally by room traders. Iron Silver

was strong, advancing from \$1.10 in April to \$2.25 in October. Breece paid three quarterly dividends of 5c. each, and in December distributed 20c., making the year's payment \$40,000 larger than in 1900. Consequently little stock was offered for sale, at the extreme prices of \$1.70 in June and \$1 in November. Alice, of Montana, though it receded from 84c. in January to 37c. in April, showed comparatively small transactions as the property is not yielding according to expectations.

## SAN FRANCISCO MINING STOCK MARKET IN 1901.

The record of the San Francisco mining stock market for 1901 shows a marked increased volume of business and wider fluctuations in prices as compared with that of 1900.

c., copper; d., diamonds; g., gold; l., lead; s., silver.

the improved facilities inaugurated and installed on the Comstock Lode during the preceding years, by which the drainage of the lower levels of the mine was to be accomplished, and electric hoists, etc., installed, for a more thorough ventilation of the ore bodies which were believed to exist in these lower levels, created expectations of a great revival of business in Comstock mining stock. Although these hopes and expectations were not fully realized, yet the moderate rally that occurred during 1901 gave a new interest and activity to the market as it had not felt for several years.

The history of the San Francisco mining stock market for some years past has been marked by extreme fluctuations, a sudden upward movement in one or two

stocks would carry prices skyward, inspiring fresh hopes in the breasts of long disheartened, assessment-paying stockholders. But this sporadic movement would last scarcely a week, and would be followed by a long period of dullness, with renewed assessments to depress the shareholders. Other booms would follow, and history would repeat itself as above. In these movements prices rarely rose above the dollar mark, and it is now nearly ten years since Comstock mining stock reached \$10 per share, and more than five years since any stock sold as high as \$5.

The confidence in the future of the Comstock lode has been further strengthened by the payment during 1901 of three dividends aggregating \$75,000, the balance going into improvements by the Consolidated California and Virginia; the abandonment of former expensive methods of mining and milling and the substitution of more efficient plants, making the large bodies of low-grade ore, formerly neglected, available; the successful work of the Davis-Calyx drill, which, by penetrating the Potosi-Brunswick ground for a depth of 800 ft., demonstrated the occurrence of paying ore bodies in unexplored ground, and the extension of the south lateral of the Comstock tunnel through the Silver City country, which will drain the Holman property of the Silver Hill Mining Co., already demonstrated to be valuable. With the new improvements under way and large bodies of low-grade ore ready for the mills, the future of the Comstock is full of bright promise.

**DIVIDENDS PAID BY AMERICAN MINES AND INDUSTRIAL COMPANIES, \$1=\$1,000;  
TOTAL, FULL AMOUNT.**

## AUSTRALASIA.

THE most important articles of mineral production in the seven colonies of Australasia are gold, silver, lead, copper, tin, iron and coal. These industries are referred to specifically under the respective captions elsewhere in this volume. The statistics of production, imports and exports as reported in the official statistics are summarized in the following tables:

MINERAL PRODUCTION OF NEW SOUTH WALES. (a) (c) (IN METRIC TONS AND DOLLARS; £1—\$5.)

(a) From the *Mineral Statistics of the United Kingdom*, except the figures for 1896, which are from the *Statistical Register of South Australia, Part IV*, and those for 1897, which are from *British Statistical Abstracts*. (b) Includes yellow metal. (c) Not reported. (d) Exported in 1896 also rock salt, 3 metric tons (\$50). In 1897, 2 metric tons (\$30). (e) No tin ore exported in 1896; but tin, block and sheet, 5 metric tons (\$1,795). In 1897 2 metric tons (\$325).

(a) From *Statistics of the Colony of Tasmania, Part V*, Production. There was also mined in 1896, 6 tons of nickel ore, valued at \$3,000. (b) Not reported. (c) Represents car-loads. (d) Included with silver-lead ore. (e) In addition there were produced 8,496 tons of copper bullion, valued at \$3,349,300. (f) In addition there were produced 9,343 tons of copper blister, valued at \$4,190,355.

(a) From *Osterr. Zeits. für Berg-, Hütten und Salinenwesen*, except the figures for 1897 and 1898, which were furnished by the "Bosnisches Bureau des K. und K. gemeinsamen Ministeriums." Besides the substances specified in the table there was also produced: In 1897, fahlore, 40 tons; in 1898, 452 tons; in 1899, 620 tons. Iron pyrites, in 1898, 3,670 tons. (b) Not reported.

## BELGIUM.

THE most important articles of mineral production in Belgium are coal, iron, lead, zinc, manganese ore and phosphate of lime. Developments in these industries are described specifically under the respective captions elsewhere in this volume. The official statistics of production, imports and exports are summarized in the following tables:

MINERAL PRODUCTION OF BELGIUM. (a) (IN METRIC TONS AND DOLLARS; 5 f.—\$1.)

| Year.     | Iron Ore. |           | Lead Ore. |         | Manganese Ore. |          | Pyrites. |         | Zinc Ore. |          |           |          | Totals.   |

(a) From *Statistiques des Mines, Minières, Carrières, et Usines Métallurgiques*, by Emil Harzé. Belgium also produced, in 1896, manganese pig-iron, 11,391 tons, \$154,160; kaolin, 130,960 cu. m., \$213,560; and in 1897, manganese pig-iron, 12,636 tons, \$199,700. (b) Not stated in the report. (c) Includes output of enamine. (d) Statistics not yet available.

(a) From Reports Compiled by the Geological Survey of Canada. (b) Estimated. (c) Includes brick, building stone, lime, sands, gravels, tiles, etc. (d) Value of tile in 1897, \$225,000; sewer pipe, \$164,250. In 1898 and 1899 sewer pipe is alone reported. (e) Oven coke, all the production of Nova Scotia and British Columbia. (f) Copper contents of ore, matte, etc., at the following values per lb.: 1897, 11¢; 1898, 12¢; 1899, 17¢; 1900, 16¢; 1901, 16¢. (g) Fine kilograms calculated at \$664.60 per kg. (h) Export returns. (i) Amount of pig iron produced from native ore; the total amount of pig iron smelted was 96,575 short tons, valued at \$1,501,698. (k) Lead contents of ores, etc., at the following values per lb.: 1897, 3¢; 1898, 3¢; 1899, 4¢; 1900, 4¢; 1901, 4¢. (m) Calculated from inspection returns at 100 gals. crude to 42 gals. refined. The value of the crude per bbl. of 35 imp. gals. was, in 1897, \$1.42; in 1898, \$1.40; in 1899, \$1.48; and in 1900 and 1901 when the ratio was 100 gal. to 54 refined, \$1.62 per bbl. (n) Silver contents of ores, values for production and exports per oz.: 1897, \$0.598; 1898, \$0.583; 1899, \$0.593; 1900, \$0.614; in 1901, \$0.595. (p) In 1897, includes mercury, 312 kg. (\$334), also sundry minerals, estimated in part and including actinolite and tripolite; in 1898, includes tripolite, 922 metric tons (\$16,660); in 1900, tripolite, 305 metric tons, \$1,950; in 1901 sundry minerals estimated in part and including actinolite, 482 metric tons, \$3,126. (q) Not reported. (r) Nickel contents of ore, matte, etc., in 1899, at 36c. per lb.; in 1900 at 47c. per lb.; in 1901 at 50c. per lb.

(a) From the tables of the *Trade and Navigation of the Dominion of Canada*. The imports figures are for home consumption only. The exports are those of domestic produce. (b) Including coal dust. (c) Represents fine copper contained in ore, matte, regulus, etc. (d) Silver contents of ores. (e) Represents lead contained in ore. (f) Includes manufactures. (g) Includes alumina. (h) Fiscal years ending June 30. (i) Not reported.

(a) From the *Annual Reports of the Bureau of Mines of Ontario, Toronto*. (b) Quantity and value included with that of plain pressed brick. (c) Comprises kerosene and naphtha. (d) Comprises gas and fuel oils and tar. (e) In 1898 total includes 221 metric tons carbide of calcium (\$34.44). In 1899, 5,300,000 paving brick (\$42,550); 965 metric tons carbide of calcium (\$74,680); 91 metric tons of talc (\$500); and 1,080 metric tons of zinc (\$24,000). In 1900, 454 metric tons zinc ore (\$500); 3,211 tons steel (\$756,626); 3,669 tons feldspar (\$5,000); 907 tons talc (\$5,000). In 1901, 1,381 metric tons zinc ore (\$1,500); 13,181 tons steel (\$347,280); 4,628 tons feldspar (\$6,375); 363 tons talc (\$1,400); 6,352 tons iron pyrites (\$17,500); 485 tons corundum (\$53,115); 2,515 tons carbide of calcium (\$168,792); 473 tons actinolite (\$3,126). (g) Not reported. (h) One barrel of crude oil is reckoned at 35 imperial gallons, and 1 barrel refined at 42 imperial gallons.

## CHILE.

THERE are no official statistics of mineral production in Chile. The exports and imports are summarized in the subjoined table. With respect to the most important articles of mineral production, namely, copper and nitrate of soda, the exports practically represent the production. This is also the case with respect to iodine and borate of lime.

MINERAL EXPORTS OF CHILE. (a) (IN METRIC TONS AND CHILEAN DOLLARS.)

(a) From the *Returns of Trade and Trade Reports of the Imperial Maritime Customs, Shanghai, China*. In these reports the unit of quantity is chiefly the "picul," and that of value the "Haikwan-tael." In converting the original data to metric tons and dollars, the following relations were used: 1 picul = 0.060453 metric ton; in 1897, 1 Haikwan-tael = 72c.; in 1898, 70c.; in 1899, 71.4c.; in 1900, 71.7c.; in 1901, 74.2c., at the average sight exchange on New York, London, Paris, Berlin, Calcutta, and Hong-Kong respectively. (b) Not reported. (c) In 1898 there was also exported 4.41 metric tons of unclassified copperware valued at \$1,321; in 1899, 0.25 metric tons (\$153); in 1900, 0.42 metric tons (\$213); in 1901, 0.12 metric tons (\$47).

# FRANCE.

THE official statistics of mineral production in France and her Colonies are summarized in the subjoined tables. With respect to the most important substances, reference should be made to the respective captions elsewhere in this volume.

(a) From *Statistique de l'Industrie Minière*. (b) Not reported. (c) Includes pure bitumen, bituminous schist, bituminous sand, and asphaltic limestone. (d) Sulphur and limestone impregnated with sulphur. (e) Wrought steel. (f) Lead produced from native ores only, and does not include the metal produced from foreign ores and bullion. (g) Finished product.

## MINERAL PRODUCTION OF TUNIS. (a) (IN METRIC TONS AND DOLLARS.)

| Year.     | Salt. |          | Lead Ore. |          | Zinc Ore. |           | (a) From <i>Annual General Reports</i> , by C. I e Neve Foster, and <i>Statistique de l'Industrie Minérale</i> . Additional products in 1898: Gypsum, 4,700 metric tons; marble, 1,000 metric tons; phosphate of lime, 1,000 metric tons; building stone (dressed), 18,000 cu. meters; stone (broken), 135,000 cu. meters. In 1899, 70,000 tons phosphate rock, valued at \$168,000; in 1900, 178,000 tons valued at \$781,000. |

(a) Statistics communicated by E. Grohmann, Seriphos. (b) Not stated. (c) There was produced also in 1896 other 40 metric tons, value, \$104; in 1899 speiss from lead smelting, 1,100 metric tons (\$12,760); in 1900, asbestos, 9 tons (\$72); soapstone, 97 tons (\$585); speiss from lead smelting, 3,767 tons (\$41,566); in 1901, asbestos, 43 tons (\$345); soapstone, 150 tons (\$1,100).

# INDIA.

Official statistics of mineral production in British India, and the imports and exports, are summarized in the subjoined tables:

MINERAL PRODUCTION OF INDIA. (a) (IN METRIC TONS AND DOLLARS; 4 rupees = \$1.)

| Alum. |          | Asbestos.<br>Kg. |      | Borax. |          | Clay.     |  | Coal.     |             | Copper Ore. |       | Fullers Earth. |       |

(a) From *Résumé Statistique de l'Empire du Japon*, Tokio, and special reports from the Japanese Government. The data contained in the table of production of the Government mines are nearly exact, but those contained in the table of private mines, being the figures furnished by the mine owners themselves, are only an approximation and considerably less than the actual figures. (b) In making the conversions from the Japanese units to metric tons, hektoliters and dollars, the following relations were employed: 1 kwan = .0037555 metric tons; 1 koku = 1,8000 hektoliters; 1 yen = \$1; 1 kg. = 32.151 troy ounces. (c) Crude product. (d) Number of liters. (f) Not reported. (g) Includes production of Government mines. (h) Number of liters. (i) Liters of crude oil.

(d) Metric tons.

## PORTUGAL.

THE mineral statistics of Portugal are summarized in the subjoined table, for which we are indebted to the courtesy of Senhor Severiano Augusto da Fonseca Monteiro, chief of the Reparticao de Minas, Ministerio das Obras Publicas of Portugal.

The statistics of mineral production in Portugal in years prior to 1896 may be found in THE MINERAL INDUSTRY, Vol. II. and Vol. VII. Statistics of the that the mineral industry of Portugal has not yet attained much importance, the output of copper and copper ore forming the chief part of the total. This is principally the production of Mason & Barry Co., Ltd.

MINERAL PRODUCTION OF PORTUGAL. (a) (IN METRIC TONS AND DOLLARS; 1 milreis = \$1.08.)

(a) From the Russian official mining report "Shornik Statisticheskikh Svedenie o Gornozavodskoi Promyshlennosti Rossie v Zavodskom Godu," St. Petersburg. (b) In the Russian reports the quantities are stated in poods and the values in silver rubles. In making the reductions the following relations were employed: 1 pood = .0168 metric ton; 1 silver ruble = 40 cents.

(a) Figures for 1897 are from the *Report of the Comisión Ejecutiva de Estadística Minera*. The figures for 1896, 1898 and 1899, are from the official *Report of the Junta Superior Facultativa de Minas*, Madrid. There was also produced in 1896, lead and zinc ores, 400 metric tons, \$400; in 1897, gold ore, 456 metric tons, \$1,850; lead and zinc ores, 40 metric tons, \$40; in 1898, lead and zinc ore, 38 tons, \$38; gold, \$2,338. (b) Not reported. (c) Represents non-argentiferous copper ore. (d) Undressed ore. (e) 70,814 tons, \$152,300, of this product is the contents of copper pyrites from Huelva. (f) Gold ore only.

(a) From *Bidrag till Sveriges Officiella Statistik*. (b) Not stated in the reports. (c) Building stone, etc., wrought and unwrought.

# UNITED KINGDOM.

THE statistics of the mineral production, imports and exports, are given in the subjoined tables. The statistics of the most important substances for 1901 will be found under the respective captions elsewhere in this volume.

## MINERAL PRODUCTION OF THE UNITED KINGDOM. (a) (METRIC TONS AND DOLLARS; £1=£5.)

| Year.     | Alum Shale.  | Arsenious Acid. | Arsenical Pyrites. | Barytes.         | Bauxite.      | Chalk.              |
|-----------|--------------|-----------------|--------------------|------------------|---------------|---------------------|
| 1896..... | <i>Nil.</i>  | 3,674 \$227,415 | 8,949 \$40,035     | 24,117 \$127,950 | 7,365 \$9,590 | 3,616,177 \$785,850 |

(a) From *Mineral Statistics of the United Kingdom*. (b) Including china clay, potters' clay, and fuller's earth; and for 1896 comprises a large quantity of ordinary brick clay not included in the returns of previous years. (d) Bog ore, which is raised in Ireland, is an ore of iron, used principally for purifying gas. (e) Not reported. (f) Not including chalk. (g) Included with granite. (h) Statistics not yet available.

Additional products: In 1897: Mica, 5,063 metric tons, \$3,435; soapstone, 23 metric tons, \$490; nickel ore, 305 metric tons, \$1,500. Metals obtainable by smelting in 1897: Aluminum, 815 metric tons, \$229,400; nickel, 7½ metric tons, \$3,250; sodium, 86 metric tons, \$63,750.

(a) From *Accounts Relating to Trade and Navigation of the United Kingdom*. (b) Number of tons shipped for the use of steamers engaged in the foreign trade. This not being an export in the ordinary acceptance of the term, the value thereof is not given in the trade returns. (c) Including naphtha, paraffine, paraffine oil and petroleum. (d) Included in exports of coal and culm for this year. (e) N. E. S. signifies "not elsewhere specified."

## UNITED STATES.

STATISTICS and full particulars of the mineral production of the United States will be found in the introduction and the articles on the different substances. We give below the mineral imports and exports for five years:

### MINERAL IMPORTS OF THE UNITED STATES. (a)

(a) From *Summary of Commerce and Finance of the United States*.

(c) Ore, so called, consisting chiefly of matte.

(e) Total exports of coin and bullion; that is, includes both domestic and foreign not elsewhere specified.

(f) Only approximately correct. The Bureau of Statistics reports only the value of silver ores exported, but a much larger amount of silver leaves the country in copper matte which is classified as copper ore and no record is kept of its silver contents. The gold in copper matte exported is not included in the exports of gold given in the above table. These figures include ore of both domestic and foreign origin.

(g) Including nickel oxide and matte.

(h) Includes chlorate, muriate, and nitrate of potash, and all other salts of potash.

(j) Reported in bbls. and reduced to gals. at 42 gals. = 1 bbl.

(k) Including slate.

(m) Calculated at 1 bbl. = 400 lb.

(n) Not enumerated.

(o) Not reported separately. Included with crude phosphates.

(p) Not reported separately. Included with antimony.

Note.—N. E. S. signifies not elsewhere specified.

# INDEX.

# The Buyer's Manual

## Preface.

---

THE advertising pages of the annual volumes of this work will well repay the careful perusal and study of every reader who wishes to be well informed upon the present condition of the mineral industry. They give an admirable and practical insight into the present state of the mining and metallurgic arts, for in them nearly every manufacturer or dealer of note in this country advertises the machines, appliances, and processes which are now in vogue, or which it is sought to introduce; while the names and specialties of the most eminent members of the engineering professions, as indicated in their cards, show the direction of modern mining and metallurgical progress.

These advertising pages are no less important to those who desire a clear knowledge of the means by which this country has come to be far the most important producer of minerals and metals than to those who wish to know where to get that full and reliable information concerning the values of properties, machinery, processes, and products which should precede the investment of capital.

Every country in the world is wisely striving to develop its mineral resources, and to build up its mineral industry, and in all of them this volume, which gives the latest and best practice in every department of the industry, has become indispensable. It is constantly consulted for the best technical skill and the most advantageous machinery and appliances in use. All enterprising manufacturers of such wares appreciate this fact, and know that in no other way can they so effectively bring their goods before those who may need them as through the advertising pages of THE MINERAL INDUSTRY. These pages have become a veritable directory of the best in everything relating to the industry, and American, German and English manufacturers there compete for the orders of the whole world. \$1,000,000,000 a year is certainly not an overestimate of the annual expenditure for technical skill, machinery and supplies used in the industry of which THE MINERAL INDUSTRY and *The Engineering and Mining Journal* are not only the chief but the only universal representatives published in any language.

# C. C. B. Pocahontas Smokeless Coal.

**The Only American Coal Officially Endorsed by The Governments of Great Britain, Germany and the United States.**

## **THE STANDARD FUEL OF THE UNITED STATES NAVY.**

### **ENDORSEMENT BY THE GERMAN GOVERNMENT.**

After making a thorough test of our Pocahontas Coal the NAVY DEPARTMENT OF THE GERMAN EMPIRE has placed it on its list of Admiralty Coals acceptable to that Department, for supplying the requirements of men-of-war, and the proposals issued by the German Government last November stated, "That bids for the coming year would be received ONLY FOR POCAHONTAS AND CARDIFF COALS ON THE ADMIRALTY LIST."

### **ENDORSEMENT BY THE GOVERNMENT OF GREAT BRITAIN.**

In March, 1894, by command of Her Majesty, a report on the coal mines of the United States was presented to the Houses of Parliament.

This report, which was made by Sir Julian Pauncefote, British Minister at Washington to the Earl of Roseberry, Secretary of Foreign Affairs, stated that "POCAHONTAS COAL IS UNDOUBTEDLY ONE OF THE BEST COALS MINED IN AMERICA FOR THE GENERATION OF STEAM."

In addition to its remarkable steaming qualities, POCAHONTAS COAL IS PRACTICALLY SMOKELESS, AND THE NAVY LEAGUE OF ENGLAND HAS OFFICIALLY STATED "THERE IS VIRTUALLY NO OTHER SOURCE OF SUPPLY OF SMOKELESS COAL OUTSIDE OF GREAT BRITAIN, EXCEPTING THE POCAHONTAS COAL OF WEST VIRGINIA."

### **ENDORSEMENT BY THE GOVERNMENT OF THE UNITED STATES.**

THE UNITED STATES NAVY DEPARTMENT for several years past has been making exhaustive tests of various coals, with a result that it has adopted Pocahontas as its standard fuel.

The annual report of the United States Geological Survey for 1900-1901, just published, states, "POCAHONTAS COAL OF WEST VIRGINIA IS THE STANDARD FOR STEAM COAL."

POCAHONTAS IS THE ONLY AMERICAN COAL WHICH HAS EVER BEEN ENDORSED BY A EUROPEAN GOVERNMENT, and these high testimonials regarding its superior steaming qualities and smokeless character from such disinterested sources, show that it is regarded both at home and abroad as equal to the best Cardiff.

ITS ADOPTION BY THE UNITED STATES NAVY DEPARTMENT AS ITS STANDARD FUEL FOR USE ON ITS CRUISERS, AND THE FACT THAT IT IS NOW PLACED ON THE ADMIRALTY LIST BY THE GERMAN GOVERNMENT ARE THE HIGHEST ENDORSEMENTS WE COULD ASK FOR, AND ESTABLISHES ITS REPUTATION AS THE GREAT STEAMING COAL OF THE WORLD.

# Stamp Milling of Gold Ores

BY

**THOMAS A. RICKARD,**

*Mining Engineer and Metallurgist, Fellow of the Geological Society,  
Associate of the Royal School of Mines, London; Member  
of Council American Institute of Mining Engineers,  
State Geologist of Colorado, etc., etc.*

## TABLE OF CONTENTS

Glossary of Stamp-Milling Terms.

This book offers a careful description of the most recent gold-milling practice in this and other countries, being a record of the results of investigations made by the author in the course of professional work during the past ten years. The author's inquiry into the principles of this important branch of metallurgy sprang from the first observation of the apparently contradictory practice of Colorado and California, in both of which States he has had charge of the operation of typical milling plants. The search for the scientific principles explaining methods so diverse led him to the general study of the reduction of gold ores and induced him to spread the inquiry over a field nearly commensurate with existing mining regions. The matter thus collected is rather a painstaking description of practice than a discussion of the chemistry and mechanics of the stamp-milling process, and is therefore quite as valuable to those engaged in the work of the mill as to the student and engineer.

# The Metallurgy of Lead

AND THE

## Desilverization of Base Bullion.

BY

**H. O. HOFMAN, E. M., Ph. D.,**

Professor of Metallurgy, Massachusetts Institute of Technology.

### CONTENTS.

#### PART I. INTRODUCTION.

CHAPTER I.—Historical and Statistical Notice.

CHAPTER II.—Properties of Lead and Some of its Compounds.

CHAPTER III.—Lead Ores.

CHAPTER IV.—Distribution of Lead Ores.

CHAPTER V.—Receiving, Sampling and Purchasing Ores, Fluxes and Fuels.

#### PART II. THE METALLURGICAL TREATMENT OF LEAD ORES.

CHAPTER VI.—Smelting in the Reverberatory Furnace.

CHAPTER VII.—Smelting in the Ore-Hearth.

CHAPTER VIII.—Smelting in the Blast Furnace.

General Smelting Operations.

Furnace Products.

#### PART III. DESILVERIZATION OF BASE BULLION.

CHAPTER IX.—Patinson's Process.

CHAPTER X.—Parkes' Process.

CHAPTER XI.—Cupellation:

A.—German Cupellation.

B.—English Cupellation.

# TRAVERSE TABLES,

With an Introductory Chapter on  
**Co-Ordinate Surveying.**

BY

**Henry Louis and George William Gaunt.**

This admirable compend will prove of the utmost practical value and advantage to mining engineers and all others interested in the subject. There are undoubtedly a great many Traverse Tables in vogue. Some of them are arranged with a degree of accuracy, while the prices of others are entirely too high for the ordinary mine surveyor and technical student. The advantages of the co-ordinate method of plotting traverses are necessarily familiar to every experienced surveyor, and at the present day it is usual to employ in ordinary underground and surface work instruments divided into single minutes, so that the tables must be calculated for this unit to be of any real use. In ordinary chaining it may be taken that it is rare for any traverse to exceed ten chains in length, whilst the limit of accuracy for such lengths is about one link. The tables are therefore calculated to five significant places (four places of decimals), so that their accuracy is about ten times as great as is attained in ordinary actual work. In arranging the tabular divisions, a plan has been adopted which experience has fully demonstrated to be convenient for active work, all the figures needed for any given angle being found at one opening of the page and in one line. This most excellent book is arranged with unusual intelligence, and the preliminary chapter is a clear and compact exposition of the methods of co-ordinate surveying.

### **CONTENTS.**

#### **CHAPTER.**

- I. Introductory — Mistakes in Mining.
- II. What Constitutes a Mine.
- III. Rock-forming Minerals and Rocks.
- IV. Physical Character of Mineral Deposits.
- V. Origin of Veins.
- VI. Filling of Mineral Veins.
- VII. Influence of Rocks on Vein Filling.
- VIII. Mineral Deposits Other than Veins.
- IX. Prospecting.

#### **CHAPTER.**

- X. Making Locations.
- XI. Patents to Mining Ground.
- XII. Early Development of Mines.
- XIII. Ores.
- XIV. Useful Earthy Minerals, etc.
- XV. Coal.
- XVI. Gold Gravel Deposits.
- XVII. Water and Its Measurement.
- XVIII. Artesian Wells.
- Useful Tables.
- Good Books of Reference.

# Cyanide Practice

BY

**ALFRED JAMES**

**Late Technical Manager and Special Expert in South Africa, New Zealand, Australia and the United States of the Company introducing the Cyanide Process.**

An exceedingly valuable and important contribution to the subject, faithfully recording the personal experience of the author in the actual working of the process, and covering a vast amount of information and data which is nowhere else obtainable. The process section of this excellent treatise embodies sufficient and requisite details to enable a mining engineer to accurately test his products, design and install efficient and economical plants, and work them advantageously. The latter portion of the book demonstrates the advances which have been made in the treatment of dry crushed and roasted ores, and in the treatment of slimes by filter press and other methods. The treatise incorporates the following divisions:—

## CONTENTS.

### INTRODUCTION.

- Chapter I. Investigation of Samples.
- II. Plant, and General Designs of Buildings and Machinery.
- III. Extraction and Method of Crushing.
- IV. Treatment of Slimes.
- V. Filter Press Treatment of Slimes.
- VI. Treatment of Sulpho-Telluride Ore.
- VII. Dry Crushing.
- VIII. Costs of Erecting Plants.
- IX. Extractor Box Work and Sump Solutions.
- X. Losses in Cleaning Up.
- XI. Bromo-Cyanide.
- XII. Assay of Gold Solutions.
- XIII. Recent Cyanide Practice and Tables.

**Royal Quarto Cloth, freely illustrated, embracing numerous diagrams and working drawings.**

# THE ORE DEPOSITS OF THE United States and Canada

By **James Furman Kemp, A.B.E.M.**

PROFESSOR OF GEOLOGY IN THE SCHOOL OF MINES, COLUMBIA UNIVERSITY.

**Third Edition. Entirely Rewritten and Enlarged, with Elaborate Illustrations.**

## ***The Recognized Authority on American Economic Geology.***

This is the only treatise extant containing an accurate and complete record of the various Ore Deposits of this Continent, and is positively thorough and reliable on the origin and modes of occurrence of the useful minerals in the earth's crust. It is specifically up-to-date and is essentially requisite to the teacher and student in economic geology, and to all practically engaged in prospecting or mining the useful minerals and metals. The present (third edition) has been faithfully revised, bringing the book up to the times, and embodying the latest theories of Ore Deposits and the most recent developments in actual mining operations. It will certainly interest even a larger number of readers than did the first edition, which won such universal commendations. It is, beyond all doubt or question, the dominant authority on the subject in any language, and everyone interested as a Teacher, Student, Geologist, Prospector, Miner or Mining Investor should certainly have THE BEST BOOK.

### **PART I.—INTRODUCTORY.**

- CHAPTER I.—General Geological Facts and Principles.
- CHAPTER II.—The Formation of Cavities in Rocks.
- CHAPTER III.—The Minerals Important as Ores; The Gangue Minerals and the Sources Whence Both Are Derived.
- CHAPTER IV.—On the Filling of Mineral Veins.
- CHAPTER V.—On Certain Structural Features of Mineral Veins.
- CHAPTER VI.—The Classification of Ore Deposits, A Review and a Scheme Based on Origin.

### **PART II.—THE ORE DEPOSITS.**

- CHAPTER I.—The Iron Series (in Part)—Introductory Remarks on Iron Ores—Limonite—Siderite.
- CHAPTER II.—The Iron Series, Continued—Hematites, Red and Specular.
- CHAPTER III.—Magnetic and Pyrite.
- CHAPTER IV.—Copper.
- CHAPTER V.—Lead Alone.
- CHAPTER VI.—Lead and Zinc.

- CHAPTER VII.—Zinc Alone or With Metals Other Than Lead.
- CHAPTER VIII.—Lead and Silver.
- CHAPTER IX.—Silver and Gold—Introductory: Eastern Silver Mines and the Rocky Mountain Region of New Mexico and Colorado.
- CHAPTER X.—Silver and Gold Continued—Rocky Mountain Region, Wyoming, The Black Hills, Montana and Idaho.
- CHAPTER XI.—Silver and Gold continued—The Region of the Great Basin, in Utah, Arizona and Nevada.
- CHAPTER XII.—The Pacific Slope—Washington, Oregon and California.
- CHAPTER XIII.—Gold Elsewhere in the United States and Canada.
- CHAPTER XIV.—The Lesser Metals—Aluminum, Antimony, Arsenic, Bismuth, Chromium, Manganese.
- CHAPTER XV.—The Lesser Metals, Continued—Mercury, Nickel and Cobalt, Platinum, Tin.
- CHAPTER XVI.—Concluding Remarks.
- APPENDIX I.—A Review of the Schemes for the Classification of Ore Deposits.

## PROFESSIONAL DIRECTORY.

---

The skill and knowledge acquired in building up in a very few years an industry whose output last year had an aggregate market value at the place of production exceeding \$1,000,000,000, are sought for by those in every land who wish to utilize its mineral resources. It is not surprising, therefore, to find American mining engineers and metallurgists in such request that their services command far higher salaries than are paid to the engineers of any other country. The names of most of the eminent men in the profession, those who have largely contributed to this marvellous growth of the mineral industry, are found in the pages of this Professional Directory. All engaged in the industry look here when they wish to find experts eminently qualified to assist them ; it is therefore not only in accord with the highest code of professional ethics but also very desirable that the names of all those most skillful in the arts treated of in this work should be found in this Directory.

Telluride, Colo.

# MANUAL OF QUALITATIVE BLOWPIPE ANALYSIS AND DETERMINATIVE MINERALOGY.

BY

**F. M. ENDLICH, S. N. D.**

MINING ENGINEER AND METALLURGIST.

LATE MINERALOGIST SMITHSONIAN INSTITUTION, AND UNITED STATES GEOLOGICAL AND GEOGRAPHICAL SURVEY OF THE TERRITORIES

BOUND IN CLOTH. ILLUSTRATED. PRICE \$4.00.

This work has been specially prepared for the use of all students in this great department of chemical science. The difficulties which beset beginners are borne in mind, and detailed information has been given concerning the various manipulations. All enumerations of species as far as possible have been carried out in alphabetical order, and in the determinative tables more attention has been paid to the physical characteristics of substances under examination than has ever yet been done in a work of this kind. To a compilation of all the blowpipe reactions heretofore recognized as correct the author has added a number of new ones not previously published. The entire arrangement of the volume is an original one, and to the knowledge born of an extensive practical experience the author has added everything of value that could be gleaned from other sources. The book cannot fail to find a place in the library or workshop of almost every student and scientist in America.

## TABLE OF CONTENTS

- Chapter I.—Appliances and Reagents required for Qualitative Blowpipe Analysis.  
Chapter II.—Methods of Qualitative Blowpipe Analysis.  
Chapter III.—Tables giving Reactions for the Oxides of Earth and Minerals.  
Chapter IV.—Prominent Blowpipe Reactions for the Elements and their Principal Mineral Compounds.  
Chapter V.—Systematic Qualitative Determination of Compounds.  
Chapter VI.—Determinative Tables and their Application.

**THE ENGINEERING AND MINING JOURNAL,**

**NEW YORK:**  
261 Broadway.

**LONDON:**  
20 Bucklersbury.

**The Copper Handbook  
For 1903.**

will be issued in January, 1903. It will cover the entire copper industry as thoroughly as is possible within the limits of a single volume, treating of the history, mineralogy, chemistry, geology and metallurgy of copper. It will also contain a very complete (and original) glossary and the most comprehensive statistical tables on copper prepared for any publication.

The principal sections of the book will be devoted to copper deposits and copper mines. The various copper bearing districts, developed and undeveloped, will be reviewed in detail, a vast amount of matter having been secured from original sources in all parts of the globe, all treated in alphabetical order, from Abyssinia to Zululand. The chapters devoted to mines, comprising the major part of the volume, will

**TREAT OF 2,000 COPPER MINES.**

and copper mining companies, scattered from New Zealand, on the south, to the Norwegian mines north of the Arctic Circle. Direct returns from these mines will be secured in the majority of cases.

**PRICES AND TERMS.**

Owing to the increased size and scope of the next annual issue, which will cover the entire globe, the price of the 1903 edition will be increased to \$5 in buckram and \$7.50 in full library morocco. This work will be mailed to any address on the habitable globe on **APPROVAL** without any advance payment whatever, and all charges will be cancelled if book is returned within one week of receipt, if unsatisfactory.

This is probably the most liberal offer ever made by any publisher, and indicates confidence in the merit of the work.

Further details will be supplied on request, but the easiest way to determine the value of the work is to order it sent on approval. The only obligation so incurred will be that of return postage, probably about 25 cents, in case the book doesn't suit. Address the author and publisher,

**HORACE J. STEVENS,**  
**309 1/2 South Street, Houghton, Mich., U. S. A.**
